Hydatid cyst involving the spleen is a rare clinical condition (0.5-4%). We report a case of multi-parasitic infection in a 62 year old female (hydatid cyst and ascaris lumbricoides infestation), confirmed during surgery. The purpose of the paper is to emphasize on the rare association of the two parasitic infections, affecting two different organs (spleen and jejunum). The combined symptomatology of the two parasites could mimic an acute surgical abdomen.

Keywords: multiparasitic infection, hydatid cyst of the spleen, ascaris

Introduction

First reported by Berlot in 1790 during an autopsy, the splenic hydatid cyst is an extremely rare disease, representing only 0.5-4% of the primary infestations. It is an endemic disease in sheep and cattle raising countries from South America, Africa, Asia, South Europe and India, with the highest incidence in Iran [1]. In Romania the incidence of hydatidosis is about 5 cases/ 100.000 people [2].

The most common organ involved in hydatid disease is the liver (75%), followed by the lung (15%). The primary involvement of the spleen is exceptional (2.5%) [3]. The primary infestation of the spleen usually takes place by arterial route, after the parasite passes two filters: hepatic and pulmonary. There is reported a venous route of infestation, through the splenic vein (portal venous system) in patients with portal hypertension [4].

Ascaris lumbricoides nematodes infect over 1 billion people annually [5]. Ascariasis is the most common soil-transmitted heminthes infestation. The parasite matures in the small intestine; most of the parasites are expelled on the 23rd week [6]. There is very little data about this combined parasitosis, hydatid cyst of the spleen and ascariasis. Also, there are no described cases in which the patient's symptomatology mimics an acute surgical abdomen.

Case report

We report the case of a 62 year old woman, from the rural area, admitted in the Surgery I Clinic from the Emergency County Hospital Tirgu Mures. She presented with a gigantic lump in the left hypochondrium associated with

pain. On admission her general status was influenced by the abdominal pain, mimicking an acute surgical abdomen. From her history we found out that the lump appeared about 2 years ago and gradually increased in size. We observe an altered general status, fatigue, dyspnea, pain in the left half of the abdomen, flatulence with the absence of intestinal transit, nausea and vomiting. From her past medical history we remark hydatid phthisic, kidney failure, a renal cyst and sinus tachycardia. Examination of the abdomen reveals an expanded abdomen, deformed by a gigantic lump in the left hypochondrium (36x31x31), which limits the respiratory movements. The lump was painful on palpation, of firm consistency, oval in shape, had a smooth surface, immobile, with muscular defense present on deep palpation in the region (Figure 1). On auscultation we observed hyperactive peristaltic sounds. The gynecologic examination was unremarkable. Her routine hematological and biochemical investigations were normal (no eosinophilia). The chest X-Ray came back normal as well, without pulmonary hydatid cysts. Abdominal CT scan reveals a gigantic tumor in the left hypochondrium (40x30x30) with many septa which incorporates the spleen, which could plead for a hydatid cyst of the spleen. The tumor displaces the stomach to the right and, caudally the transverse and left colon.

Considering the altered general status we discarded the preoperative antiparasitic treatment and proceeded with the surgical intervention. The procedure took place under general anesthesia. A left subcostal laparotomy, extended to the right - á la LeClerc (Figure 2) was performed. Surgical exploration revealed a gigantic tumor of approximate 35x30x30 cm that pushes the stomach to the right and the left kidney infero-medially, delimited by the mezoco-

lon and splenic flexure of the colon (Figures 3 and 4). The tumor was adherent to the diaphragm. We detached the colon with the Ligasure Impact and Ligasure Atlas devices (Figure 5) and punctured the cystic tumor to avoid dissemination in the peritoneal cavity (on puncture we evacuate a clear fluid). In order to treat any potential contamina-

tion we apply isolations soaked in alcohol. We evacuate the cyst wall, encircling many solices. On our section there was around 5 litres of hydatid fluid (Figure 6). A total splenectomy was performed, with the help of the Ligasure devices, taking special care of the tail of the pancreas and splenic flexure of the colon (Figures 7 and 8). Systematic explora-

tion of the peritoneal cavity revealed the concurrent infection with *ascaris lumbricoides* (two adult parasites in the proximal jejunum) (Figure 9) but no surgical act was taken because of the known complication of fistulae in these type of infections (Figures 10 and 11). Postoperative treatment with Albendazol 2x400 mg/day was prescribed as soon as normal bowel movement is reestablished. The postoperative course was uneventful, the patient being discharged on the 7th day with additional Albendazole treatment.

Discussions

The splenic hydatid cyst has a slow development of 1-2 cm/year in diameter [7]. The latent period of cyst development is usually long: 5 to 20 years. Splenic hydatid cysts develop insidiously and may reach a large size. Clinical manifestations of hydatid splenic disease are usually mild and non-specific. The main symptom in gigantic cysts [8] is abdominal pain associated to a dyspeptic syndrome and weight loss [7,9].

Main differential diagnoses of splenic hydatidosis are splenic cystic lesions such as dermoid cyst, pseudocyst, abscess, intrasplenic pancreatic pseudocyst, pseudocyst from splenic trauma, infarcting infection, haematoma, metastatic disease and cystic lymphangioma or hemangioma. If eosinophilia is present, other parasitosis may be taken into account [10,11].

Symptoms like: abdominal pain, loss of appetite, absence of bowel movement, nausea, vomiting, fatigue are unspecific and common for both parasitic infestations (hydatidosis and ascariasis) [12].

Total splenectomy is the preferred approach undertaken in cases with large, multiple and symptomatic cysts, with the removal of all the parasitic tissue. Partial splenectomy, cyst enucleation or omentoplasty after partial resection of the cyst wall are surgical options for the treatment of splenic hydatidosis, but these techniques are used for superficial cysts, cysts localized in one pole of the spleen or cysts that are unresectable due to extensive adhesions. Par-

tial splenectomy is a hemorrhagic intervention because it is difficult to have vascular control when incising the splenic tissue, whereas unroofing the cyst wall leaves behind the pericystic layer and a residual cavity which carries the risk of postoperative infection [13].

It is important that we mention the contribution of the Ligasure devices. Using them we had the possibility to approach hidden anatomic spaces, making resections and in the same time hemostasis. It is also worth mentioning that we used these devices without any risks in flammable substances (the alcohol used to neutralize the parasites).

The main control strategy against soil-transmitted helminthes is the medical treatment with Albendazole, being cost-efficient and easy to administer [14].

The association of two parasitic infections is rare and usually found in immunocompromised patients with poor social status. Infestation with helminthes is usually a intra-operative finding.

Conclusions

The multiparasitic infection, with *ascaris lumbricoides* and splenic hydatidosis, which together mimic an acute surgical abdomen gives this case report unicity.

The antiparasitic treatment is the most important measure to treat a parasitosis. Regarding the surgical intervention, it must be carefully selected in cases where the patient's status allows it, being considered a second line treatment.
