THE INFLUENCE OF SYNTHESIS TEMPERATURE ON MANUFACTURING AND PROPERTIES OF SrSi2O2N2:Eu2+ POWDERS

This paper presents the results of the synthesis temperature on the properties of the ceramic powders of SrSi2O2N2:Eu2+obtained by the solid-phase reaction. Synthesis was carried out in the temperature range of 1250-1650°C for 2 hours in nitrogen flow in the reducing atmosphere of the graphite furnace. The phases present in the resultant powders were identified by X-ray structural analysis (XRD). Scanning electron microscopy (SEM) was used to examine the changes in the powder morphology as a result of the synthesis. The excitation and emission spectra measurements let to study phosphor photoluminescence properties. The results show the strong influence of temperature synthesis on the formation and purity of expected phases. The synthesis temperature also affects the luminescent properties of SrSi2O2N2:Eu2+ ceramic powders.

Keywords: luminescence, LED, oxynitrides

1. Introduction

Over the years, the light sources were changing. The phosphor’s discovery and their later over 100 years history of scientific research completely changed the acquisition of light. In the early 20th century German scientist prepared diverse sort of phosphors mainly based on alkaline earth chalcogenides showing the luminescence properties. Further research contributed to fluorescent lamp introduction [1]. The fluorescent lamp with the phosphor coating application led to pre-empt the incandescent lamp, known for its relatively low luminous efficacy about 15 lm/W and short operating life usually no longer than 1000 h. Fluorescent lamp made from soda-lime glass tube filled with the noble gas, mercury and the phosphor coating on the inner surface of the tube demonstrate higher efficiency 80-100 lm/W and long operating life of 10000-20000 h. The development of the calcium halophosphate phosphor (Sb3+, Mn2+ activated Ca5 (PO4)3 (Cl, F)) with blue and orange-red emission bands was the turning point in fluorescent lightning. The progress in efficiency was obtained by blending halophosphate phosphor with a red emitting phosphor (Sn2+ activated strontium orthophosphate). The commercially available fluorescent lamp consisted of a red emitting phosphor with a phosphor coating on the inner surface of the tube [2].

The progress in the LED technology and the invention of a blue diode quickly contributed to the discovery of white LEDs as a combination of the UV LED chip with blue, green, and red phosphors. This invention opened the way to use LED as a source of light in daily life. Presently, the most popular white LED is a mixture of an InGaN blue chip with yellow phosphor of YAG:Ce3+ [3]. This phosphor shows excellent quantum efficiency but because of a low rendering index (CRI) value and high color temperature cannot be applied as an indoor illumination [4]. This problem can be solved if YAG:Ce phosphor is replaced by nitrides and/or oxynitrides because of their excellent properties, such as chemical and thermal stability, non-toxicity and high luminescence emission and excitation with rare earth (RE) ions [5]. Lately, oxynitride phosphor with a formula of MSi2O2N2:Eu2+ (M = Sr, Ba, Ca) has been reported as a new perspective material for green – yellow, blue and yellow phosphors in application for white LEDs. Especially, SrSi2O2N2 phosphor activated with Eu2+ is very interesting because of its ability to emit greenish-yellow light under UV-blue radiation [6-7]. Furthermore, the emission color of this phosphor can be controlled by increasing Eu2+ concentration [8]. Most of the up to date papers on this phosphor have focused their interest on the luminescence properties, the crystalline structure and modification of the lattice structure by other alkaline earth ions [9-11]. Manufacturing of the oxynitride phosphors was reported by using the solid state reaction in forming gas, sol-gel method or carbothermal reduction and nitridation [12].

The purpose of this study was to determine the effect of synthesis parameters on the phase composition, powders...
morphology and luminescence properties of SrSi₂O₂N₂:Eu²⁺ phosphor if the reaction was conducted in the flowing nitrogen in the graphite resistance furnace.

2. Experimental

SrSi₂O₂N₂:Eu²⁺(4%) was prepared by a solid-state reaction of commercial, high purity powders. A mixture of Si₃N₄ (UBE, 98%), SiO₂ (Merck, 99%), SrCO₃ (Aber, 99.99%), Eu₂O₃ (Treibacher, 99.99%) was homogenized in an agate mortar with addition of acetone and then powders were dried in 80°C. The ratio between Si₃N₄ and SiO₂ was 1.8:0.2. Synthesis was conducted in a graphite furnace (Thermal Technology) in a nitrogen flow in the reducing atmosphere (nitrogen, purity 99.999%). All samples were hold for 2 hours at various temperature (1250-1650°C). Heating rate was 10°C/min. After synthesis, powders were pulverised in an agate mortar. The morphology of powders was studied by Scanning Electron Microscope (SEM) HITACHI S-3400N which registered secondary electrons image (SE). The photoluminescence properties and phase composition were measured in Institute of Experimental Physic at the University of Gdansk. Phase composition of the resultant samples was identified using powder X-ray diffraction method (Bruker, D2PHASER) with Cu Kα1=1.54 Å. Samples were measured in the 2θ range from 10° to 65°. The spectra of emission were

measured by Horiba FluoroMax-4P spectrofluorometer equipped with a 150W Xe arc lamp and R928P photomultiplier. All measurements were performed at room temperature.

3. Results and discussion

Figure 1 shows the morphology of SrSi₂O₂N₂:Eu²⁺ powder after synthesis at different temperature. A strong impact of synthesis temperature on powder particle morphology is clearly visible. After synthesis at lower temperature (1250-1350°C) powder particles are fine, their size is close to the size of the initial materials. If synthesis was conducted at higher temperature (1400°C) then particles form larger aggregates (Fig. 1c) with average size of 1-5 μm. The most significant difference in particles morphology can be observed after synthesis at 1450-1550°C temperature since large particles with rounded edges are noticeable. Fragile and sharp edged small particles apart from the large ones were observed after synthesis at the highest temperature (1650°C). The morphology of particles after annealing at temperature over 1400°C may indicate the presence of glassy phase.

The XRD patterns of SrSi₂O₂N₂:Eu²⁺ obtained at various temperature are shown in Figure 2. The reference diffraction pattern of Sr₁.₀₂Si₂O₂N₂ (ICDD 01-076-3141) is placed at the bottom of the picture. The temperature increase influenced the main phase crystallization. In all tested samples the expected triclinic Sr₁.₀₂Si₂O₂N₂ phase (ICDD 01-076-3141) was detected and for samples synthesized in the temperature range of 1400-1550°C this triclinic phase was the main phase. The pure triclinic phase, was obtained for samples synthesised at 1450°C and 1500°C. If synthesis was carried out at lower temperature (1250, 1350°C) then the unreacted phase of Si₃N₄ (marked on Fig. 2 as *) and Sr₂SiO₄ (#) were observed. Silica with strontium oxide form a low melting eutectic (at 1358°C) and this phenomenon can cause formation of the liquid phase at higher temperature. Presence of the liquid phase may support crystallization of triclinic Sr₁.₀₂Si₂O₂N₂ phases as it was shown previously [13]. The samples synthesized at 1650°C showed decomposition of triclinic Sr₁.₀₂Si₂O₂N₂ and formation of the unknown phase accompanied by a significant amount of amorphous phase. The remaining peaks were not unequivocally identified in a view of a large number of potential phases. Details of the investigated samples are collected in Table 1.

Figure 3 a and 3b presents emission spectra of the selected phosphor samples obtained at 1250-1550°C under λ = 350 nm excitation. The spectra consist of single emission bands in the

Fig. 2. XRD pattern of phosphor powder prepared at various temperature. Si₃N₄ (ICDD 01-071-6479) marked as * and Sr₂SiO₄ (ICDD 00-039-1256 and 00-038-0271) marked as #. The reference pattern of Sr₁.₀₂Si₂O₂N₂ (ICDD 01-076-3141) is given at the bottom of the picture.
range of 460-700 nm, peaking at 540-550 nm that can be ascribed to the \(4f^65d\rightarrow4f^7\) transition of the Eu\(^{2+}\) ions. In Figure 3a the relative emission intensity of each sample was preserved, while in Fig 3b the spectra were normalized.

Figure 3a shows influence of synthesis temperature on emission intensity of the phosphor. The luminescence intensity rises with synthesis temperature, reaching maximum for the specimen obtained at 1450°C. Above this temperature emission intensity was lower. Figure 3b shows that the peak wavelength of the emission band shifts when the synthesis temperature increases from 1250 to 1450°C, which is accompanied by the narrowing of the emission band. Comparing those spectra with XRD results it is possible to consider the influence of secondary phases on the emission spectrum in both phosphors: the considerable amount of strontium silicate in 1250°C specimen results in broader and shifted emission spectrum while the emission band is narrower for the specimen with dominating strontium oxynitride in specimens derived at temperature over 1350°C. Samples prepared at the temperature range of 1450-1550°C show the same position of emission peaks. Decrease of emission intensity at 1550°C is related to the total decomposition of SrSi2O2N2 (Fig. 2) and migration of Eu\(^{2+}\) to the non-identified compound or to the amorphous phase. The same position of the emission peak as in the SrSi2O2N2 (Fig. 3b) indicates the same coordination environment of Eu\(^{2+}\) ion in the new compound or in amorphous phase.

4. Conclusions

Green emitting phosphor with a designed formula of Eu\(_{0.04}\)Sr\(_{0.96}\)Si\(_2\)O\(_2\)N\(_2\) has been synthesized by the solid state reaction in various temperature range. The particle morphology and photoluminescence intensity were largely dependent on the synthesis temperature and the resultant phase composition. Synthesis carried out at temperature of 1400-1450°C facilitated manufacturing the phosphor powder of high-purity. Unreacted silicon nitride was observed after synthesis below 1400°C and it negatively affected emission of specimens. The highest emission intensity was obtained after synthesis at 1450°C. Synthesis at temperature at 1550°C led to reduction of emission intensity as a results of decomposition of triclinic strontium oxynitride main phase to amorphous and unidentified phases was observed at 1650°C.
