Abstract

Tobacco (Nicotiana tabacum L.) plants are known to present high levels of secondary metabolites that increase with the plant age. Molecular biology techniques like restriction enzyme digestion and PCR, requires as pre-requisite the isolation of genomic DNA of suitable purity, good quality and with low levels of contaminants. Several methods to isolate pure and intact tobacco DNA for molecular research purposes have been developed. In this work, a combination between a tobacco seed germination technique using gibberellic acid and a fast and simple genomic DNA extraction method from 14-days old tobacco seedlings to reduce the secondary metabolites levels in the final samples was presented. Ten tobacco genotypes were used to evaluate this method. The DNA concentrations were in a range between 0.73 µg/µL to 1.47 µg/µL for Habana-2000 cv. and Criollo cv., respectively. The absorbance ratios values to determine DNA quality were acceptable. This method allows the obtaining of high molecular weight DNA suitable for digestion with restriction enzymes, EcoRI and BamHI. Tobacco seedlings DNA in a short period of time, in a simple way and with a low cost, was obtained with this extraction method.

Keywords: tobacco, seedlings, genomic DNA, enzymatic digestion.

Introduction

The genomic DNA extraction from tobacco (Nicotiana tabacum L.) adult plants, sometimes results in a long and laborious process. It has been found that DNA extracts from plant tissues which have already passed the bud formation stage are problematic and unstable under storage conditions for long periods of time [1]. The final DNA quality and concentration obtained varies and depends on the starting material (Dark, Burley, Flue-cured, Oriental, etc. tobacco), on the presence of secondary metabolites such as polyphenols, polysaccharides, tannins and terpenoids, as well as the extraction protocol itself.

To reduce the presence of contaminants, the extraction is made from young tissues that have low concentrations of secondary metabolites [2, 3, 4]. These may undergo rapid oxidation during tissue rupture, irreversibly bind to DNA and co-precipitate during the process, and then prevent their use in PCR, restriction enzyme digestion or sequencing, due to inhibition of polymerases or endonucleases [4, 5, 6]. Numerous protocols have been established to isolate pure and intact DNA from plants, but many of these consume considerable time, large amounts of plant tissue and only allow a few samples to be processed. On the other hand, various commercial kits are available to extract genomic DNA from plants with sufficient quality, but sometimes the yield is low. In addition, the...
cost is particularly expensive when it is required to analyze a high number of samples [7, 8, 9].

The objective of this work was to present the combination of tobacco seed germination promoted by gibberellic acid with a simple, fast and reliable method for extracting genomic DNA from 14-day old tobacco seedlings.

Material and Methods

Plant material
Fifty seeds of each 10 tobacco cultivars (Table 1) were placed inside a Petri dish containing a qualitative filter paper (Whatman, UK) moistened with 0.015% gibberellic acid solution (GA3) (Sigma-Aldrich, USA). Plates were coated to create a moist chamber and incubated at 22° C at a rate of 16 hours light / 8 hours darkness, for two weeks. The 14-day-old seedlings (about 10-15 plantlets with mean height 1.0 ± 0.2 cm) were harvested for extraction of genomic DNA. (Fig. 1).

Fig. 1. The 14-day tobacco seedlings from which genomic DNA extraction was performed. It is important to remove the seed remains (black arrows) to avoid contamination.

Reagents and Solutions
- **Extraction Buffer (EB):** 200mM Tris-HCl, pH 8; 150 mM NaCl; 25mM EDTA; 0.5% SDS (modified from [10])
- **P:C:I Solution:** Phenol (equilibrated with 10mM Tris-HCl, pH 8; 1mM EDTA): Chloroform: Isoamilic Alcohol (25:24:1)(v/v/v)
- **Chilled Isopropanol (-30°C)
- **Ethanol 70%
- **TE Buffer:** 10mM Tris-HCl pH 8; 1mM EDTA pH 8.

DNA extraction method
- Place in a 1.5mL vial, about 30mg of seedlings with 200µl EB. Incubate at RT for 5 minutes
- Homogenize manually with an Eppendorf homogenizer until no visible pieces remain. The solution turns greenish.
- Invert the vial 3-4 times and vortex.
- Add 500 µL of P: C: I Solution and vortex.
- Centrifuge at 13000rpm/1 minute. Collect the upper aqueous phase, discard the rest.
- Add a same volume of chilled isopropanol. Invert 3-4 times and incubate 30 minutes/-30°C.
- Centrifuge at 10000rpm/5 minutes. Discard supernatant.
- Wash the pellet with 500 µL of Ethanol 70%. Centrifuge at 13000rpm/1 minute.
- Eliminate the ethanol by inverting the tube. Give a centrifuge spin, eliminate remain ethanol at the bottom with a 20-200 µl micropipette or similar.
- Leave to dry in a thermostat bath or thermal block at 65°C for 10 minutes, until the smell of ethanol disappears.
- Resuspend the DNA with 50 µL of TE Buffer, sterile or bidestilled water.
- Storage at 4°C for immediate use o at -30°C for later use.

DNA Quantification
The absorbance of the samples at 260nm, 280nm and 320nm [11] was determined on a UV / Visible Spectrophotometer (Thermo Scientific, USA) and the DNA concentration was calculated by the formula:

\[ \text{ADN (µg/µL)} = (\text{Abs}_{260nm} - \text{Abs}_{320nm}) \times \text{dilution factor} \times 50 \times 0.001 \]

Evaluation of DNA quality
The absorbance ratios (Abs_{260nm}-Abs_{320nm}) / (Abs_{280nm}-Abs_{320nm}) were calculated and samples with values within the range of 1.6-2.0 were considered as DNA of good quality.

In addition, to verify the integrity and quality of the obtained DNA, a 0.8% agar gel electrophoresis was performed and a 1% agar gel electrophoresis after samples digestion with the restriction enzymes EcoRI and BamHI (Promega, USA) for 4 hours, according to the manufacturer’s specifications. For both electrophoresis, 8 µl of the undigested or digested DNA + 2 µl Blue / Orange 6X Loading Dye (Promega, USA) was placed in each well. Phage λ DNA (Sigma-Aldrich, USA) was used as the molecular weight marker. Both gels were run at 120V / 1hour.

Staining was performed by incubating the gel with 500 mL of a solution of SYBR® Green I (dilution 1/10000) (Sigma-Aldrich, USA) for 30 minutes in the dark. The gels were visualized with a transilluminator (Vilber-Lourmat, France).

Results and Discussions
For all genotypes seed germination percentages higher than 95%, were obtained in the 14-day period (Figure 1). GA3 is capable of promoting germination and causing the rupture of the
characteristic cyclic dormancy of tobacco seeds, particularly, in those seeds stored for several years (Juan Luis Pérez, Cuba Nicotiana Germplasm personal communication). With this genomic DNA extraction method can be processed in our laboratory up to 60 samples per day. In addition, the use of the combination homogenizer-EB reduces the duration time of the extraction step to one minute. The presence of NaCl in the EB allows the removal of the polysaccharides and proteins that are bound to the DNA and increases the solubility of these two biomolecules (have a solubility similar to that of DNA) in isopropanol or ethanol, which reduces their co-precipitation with the DNA in the polar solvents [6, 9, 12]. On the other hand, EDTA, a chelating agent, traps divalent cations such as Mg$^{2+}$ and Ca$^{2+}$ and inhibits the action of nucleases that require these ions for their enzymatic activity [13, 14]. SDS detergent is able to dissolve the lipids of cell membranes and thus releasing cytoplasmic and nuclear contents [15].

The DNA extraction step with the P: C: I solution allowed to recover about 400 μl of the aqueous phase and the removal of polysaccharides, lipids, polyphenols and other non-polar compounds from the aqueous phase [16], resulting in clearer and higher quality DNA.

All values of the absorbance ratios were maintained in the range of 1.6-2.0 (Table 1) in compliance with the quality parameters established in Materials and Methods. The DNA concentrations were between 0.73 μg / µl for the cultivar Habana-2000 and 1.47 μg / µl for the cultivar Criollo. These concentration values are suitable for subsequent uses of DNA in the laboratory in techniques such as PCR or restriction enzyme digestion where quantities as low as 7.5-50 ng or 0.8-1 μg / µl, respectively, are employed. It is evident that using the protocol it can be obtained high molecular weight DNA and decreases the presence of nucleic acids of low molecular weight (Figure 2a). Furthermore, a significative smear effect is not observed as a result of a DNA degradation process. The highest concentration DNA samples isolated, which underwent the enzymatic digestion process with EcoRI and BamHI, were succesfully digested, showing a clear, constant and reproducible banding pattern across all samples and (Figure 2b) demonstrating the efficiency of the method developed in this study.

It is also important to note the influence of the mass of the starting plant material for extraction. Although the expected DNA yield of a small mass samples should be low, the chances that contaminants co-precipitate with the DNA are also low, due to the fact that during the precipitation the concentrations of saturation won’t be reached or exceed.

To my knowledge, it is the first reliable and simple method for the isolation of N. tabacum seedlings genomic DNA free from certain secondary metabolites like phenols. Since the Department of Genetics and Phytopathology from the Tobacco Research Institute, Cuba began with the interest in isolating large amounts of DNA, we chose

species of genus *Nicotiana* and cultivars of *N. tabacum* [17, 18]. The amounts and classes of secondary metabolites we can find in plants can vary considerably, that is why is unlikely that an ideal contaminant-free nuclear DNA extraction method will ever be developed. However, it is possible that the *N. tabacum* genomic DNA extraction method presented in this study can be used to isolate nuclear DNA from a variety of other plant species specially the related with Solanaceae family an the genus *Nicotiana*. The extraction method of genomic DNA described here will be useful for molecular, population genetics and breeding approaches in *N. tabacum*.

### Conclusions
The present study described the combination of gibberellic acid for quick tobacco seed germination with an extraction method of genomic DNA from 14-day old tobacco seedlings. The method is fast, economical, simple and does not require the use of hazardous compounds such as liquid nitrogen. A clearer and good quality DNA from different tobacco types was obtained, indicating the suitability of the method for different *N. tabacum* cultivars. The DNA yield was enough for posterior uses like the digestion with restriction enzymes where a clearer banding pattern demonstrated the DNA integrity obtained.
