ABSTRACT

The effect of silicon (Si) supplementation (0.35 g Na₂SiO₃ kg⁻¹ soil, 2.73 mmol Si kg⁻¹ soil) was studied in drought-stressed pistachio (Pistacia vera L. ‘Ahmadaghaii’) plants under field conditions. Silicon treatment significantly increased plant dry weight and relative water content under drought stress. The application of Si for drought-stressed plants improved the maximum quantum yield of PSII. A reduction in the net assimilation rate due to drought stress was alleviated by Si application, accompanied by an increase in stomatal conductance. Silicon treatment resulted in higher catalase and superoxide dismutase activities and lower lipid peroxidation in the leaves of drought-stressed plants. The results suggest that supplementation of water-deficient pistachio plants with Si alleviates the adverse effects of drought due to its enhancement of photochemical efficiency and photosynthetic gas exchange, as well as an activation of the antioxidant defence capacity in this species.

Key words: antioxidant defence system, net CO₂ assimilation rate, quantum yield of PSII, relative water content

Abbreviations:

INTRODUCTION

Abiotic stresses such as drought, high salinity and extreme temperatures are major causes of crop losses worldwide. Drought is an important environmental stress that adversely affects plants growth and causes reduction of growth rate, stem elongation, leaf expansion and stomatal movements (Chaves et al. 2003).

Drought stress triggers production of reactive oxygen species (ROS) that cause oxidative damage to proteins, membrane lipids and other cellular components. To keep this damage to a minimum,
plants possess enzymatic and non-enzymatic antioxidative defence systems. Enzymes such as superoxide dismutase (SOD), ascorbate peroxidase (APX) and catalase (CAT) play an important role against oxidative stress (Apel and Hirt 2004). Under drought conditions, the increased activity of antioxidant enzymes is important for plants stress tolerance (Gong et al. 2005).

It has been well documented that elements such as aluminium, cobalt, sodium, selenium, and silicon positively affect plant growth and stress resistance (Broadley et al. 2012). Although not considered an essential element for plants growth and metabolism, silicon (Si) is beneficial for most of the higher plants, especially under stressful conditions (Ma 2004, Epstein 2009). Silicon alleviates the effects of salt stress, high temperature and heavy metal toxicity in plants (Shi et al. 2005, Liang et al. 2007, Shen et al. 2010).

Silicon application to crops has been reported to enhance their tolerance of water stress (Ma 2004, Hattori et al. 2007). The mechanisms that underlie Si-mediated alleviation of damages caused by drought stress are poorly understood (Chen et al. 2011). Several authors have suggested that Si causes an improvement of water use efficiency and stimulates enzymatic and non-enzymatic antioxidative defence systems (Liang et al. 2003, Hattori et al. 2005, Gunes et al. 2007, Liang et al. 2007, Cooke and Leishman 2011). An increase in the production of antioxidants and a decline of ROS generation mediated by Si causes a reduction of photo-oxidative damage, maintenance of chloroplast membrane integrity and thus enhancement of plant drought tolerance (Warraich et al. 2011). Silicon fertilisation leads to increased volume and weight of roots (Matichenkov et al. 2000, Ahmed et al. 2011, Sonobe et al. 2011) and decreases water loss via transpiration because of the silicification of leaf surfaces (Cooke and Leishman 2011) that decreases cuticular transpiration as well as a reduction in the diameter of stomatal pores (Snyder and Matichenkov 2007). All of these factors can ultimately enhance drought resistance of Si-supplemented plants.

Pistachio (Pistacia vera L.) is one of the most important tree crops in the Mediterranean climate, where plants are frequently subjected to prolonged drought periods (Rieger 1995, Gijón et al. 2011). Pistachio is an important crop in Iran and the area of pistachio orchards in the country is more than 360,000 ha, with about 13 million pistachio trees (Sheibani et al. 1994, Banakar and Ranjbar 2010) comprising 60 different varieties.

Pistachio is a drought tolerant species (Gijón et al. 2010, 2011). However, responses of pistachio to water stress have not been adequately characterised. There are few studies on the water relations of this species (Gijón et al. 2010). It has been shown that drought tolerance of pistachio plants was higher than some other fruit trees and other typical xerophytes species (Gijón et al. 2011). Despite its potentially high drought tolerance, any amelioration of drought-induced growth suppression in this species requires further improvement of plant ability to maintain homeostasis in water relations, especially during the summer season. Previous studies on the effect of Si supplementation in drought-stressed plants have mainly focused on Gramineae species (Gong et al. 2005, 2008, Ahmed et al. 2011, Sonobe et al. 2011). We hypothesised that, similar to that in Gramineae, Si supply will improve drought tolerance of pistachio plants, a drought-resistance dicotyledonous species.

The aim of this work was to study the mechanisms for alleviating the effect of Si in drought-stressed pistachio plants with regard to Si-mediated alteration of some physiological characteristics under water scarcity. For this purpose, we examined growth, relative water content, chlorophyll (Chl) fluorescence parameters and gas exchange patterns, and studied the effect of Si on the antioxidative defence system during drought stress.

**MATERIAL AND METHODS**

**Plant growth and treatments**

Seeds of pistachio (Pistacia vera L. ‘Ahmadaghaii’) were sown in the top parts of cylindrical plastic pots; four seeds were planted in each pot. Pots were 14 cm in diameter and 105 cm in depth, filled with 15 kg sandy loam soil (pH 7.6, EC 1.32 dS m⁻¹, field capacity [FC] 23%, organic carbon (OC) 1.09 %). For the basal fertilisation, 200 mg nitrogen kg⁻¹ soil as NH₄NO₃ and 50 and 62.5 mg phosphorus and potassium kg⁻¹ soil as KH₂PO₄ were applied. Before filling the pots, soils of Si treatments were fertilised with 0.35 g sodium metasilicate (Na₂SiO₃) kg⁻¹ soil (3.44 mmol dm⁻³ soil, 2.73 mmol kg⁻¹ soil). Equimolar concentrations of NaCl were applied for balancing Na amounts in the soils of control pots without Si. After emergence, the seedlings were thinned to one plant per pot and plants were watered every 4-5 days to maintain at 70% of FC before starting treatments. Seventy-five days after sowing, different watering treatments including...
the control (70% FC) and drought (35% FC) were applied. Four independent pots were counted as the four replicates for each treatment combination. Plants were grown under field conditions located near the city of Miandoab, NW Iran (46º6' E and 36º46' N) with day/night temperature of 20-35/17-20°C, relative humidity of 25-45% and daily photon flux density of about 1,200-1,700 µmol m² s⁻¹ throughout the experimental period.

**Plant harvest, Si analysis and measurement of relative water content (RWC)**

Plants were harvested 45 days after starting different watering regimes (120 days after sowing). Shoots were washed with distilled water, blotted dry on filter paper and after determination of fresh weight (FW) were dried for 48 h at 70°C for determination of dry weight (DW). Leaves were prepared for determination of Si (Jaiswal 2004) using Inductively-Coupled Plasma-Atomic Emission Spectrometry (ICP-AES, INTEGRA XL 2, GBC, Australia). Relative water content (RWC) was measured in the leaves harvested at 1 h after light on in the field and calculated according to the formula: (FW – DW)/(TW – DW) × 100 where TW is turgid weight. Before the harvest, leaf Chl and gas exchange parameters were determined in the second or third youngest, fully developed leaves.

**Measurements of Chl fluorescence parameters and photosynthetic gas exchange**

Chlorophyll fluorescence parameters were recorded using a portable fluorometer (OSF1, ADC Bioscientific Ltd., UK) for both dark adapted and light adapted leaves. Leaves were acclimated to dark for 30 min using leaf clips before measurements were taken. Initial (Fo), maximum (Fm), variable (Fv = Fm – Fo) fluorescence as well as maximum quantum yield of photosystem II (PSII) (Fm/Fo) were recorded. Light adapted leaves were used for the measurement of steady state (F₀) and maximum (Fm’) fluorescence. Calculations were made for Fm’ (Fm’ = Fm/[(Fo/Fm) + (Fo/Fm’)]) [Miquel and Johnson 2000]. Net CO₂ fixation (A, µmol m⁻² s⁻¹), transpiration rate (E, µmol m⁻² s⁻¹) and stomatal conductance to water vapour (gs, mol m⁻² s⁻¹) were measured with a calibrated portable gas exchange system (LCA-4, ADC Bioscientific Ltd., UK) after 5 h into the light period under a photon flux density of about 1,500 µmol m⁻² s⁻¹.

**Assay of enzyme activity and related metabolites**

Activity of superoxide dismutase (SOD, EC 1.15.1.1), peroxidase (POD, EC 1.11.1.7), catalase (CAT, EC 1.11.1.6) and ascorbate peroxidase (APX, EC 1.11.1.11) were determined according to methods described elsewhere (Habibi and Hajiboland 2010). Lipid peroxidation was estimated from the amount of malondialdehyde (MDA) formed in a reaction mixture containing thiobutiric acid. The concentration of hydrogen peroxide (H₂O₂) was determined using the potassium titanium-oxalate method (Habibi and Hajiboland 2010). Soluble protein was estimated using the Bradford method (1976).

Statistical analyses were carried out using Sigma stat (3.5) with the Tukey test (p < 0.05).

**RESULTS**

The fresh and dry weight of plants decreased significantly under drought stress conditions in both Si treatments. However, the extent of reduction in plant biomass was lower in the presence of Si. Silicon treatment did not influence plants’ FW, DW and RWC under well-watered conditions, while it significantly increased these parameters under drought conditions. The silicon concentration of leaves was significantly higher in the Si-treated plants (Tab. 1).

Alleviation of drought stress by Si in pistachio

Drought stress decreased the maximum quantum yield of PSII ($F_{v}/F_{m}$) and effective quantum yield of PSII ($\Phi_{\text{PSII}}$). In contrast, photochemical quenching ($qP$) was not influenced by different watering treatments and non-photochemical quenching ($qN$) rather increased under drought conditions. Similar with plant growth data, Si supplementation did not affect the photochemical parameters in well-watered plants but improved the $F_{v}/F_{m}$ ratio and decreased $qN$ in drought-stressed ones (Tab. 2).

The net assimilation rate ($A$), transpiration rate ($E$) and stomatal conductance ($g_s$) all were inhibited by exposure of plants to drought stress. Application of Si influenced these parameters under both watering regimes. In well-watered plants, the net assimilation rate was increased slightly due to Si application; this effect was significant for $E$ and $g_s$. The effect of Si application was more prominent under drought conditions. Because of a simultaneous increase of the net assimilation rate and transpiration following elevated stomatal conductivity, the water use efficiency ($WUE$) was improved significantly.

conductance by Si treatment, water use efficiency (WUE) remained unchanged (Tab. 2).

Drought stress caused a significant increase in the activity of SOD and APX, but did not change the activity of POD while it rather decreased that of CAT (Fig. 1). The application of Si stimulated SOD and POD activity under well-watered conditions, but did not influence CAT and APX activity. Under drought conditions, Si application caused a significant increase in the activity of all analysed antioxidant enzymes with the exception of APX. Drought stress resulted in a significant accumulation of MDA and \( \text{H}_2\text{O}_2 \). Although Si application had no effect under well-watered conditions, Si supplemented plants maintained lower MDA content under drought stress (Fig. 1).

Two-way analysis of variance of the effects of drought and Si application revealed that Si influenced the majority of the measured physiological parameters in pistachio leaves (Tab. 3). A significant interaction effect between Si and drought on plant growth, RWC, SOD and

CAT activity and MDA content also indicated that Si influenced these parameters mainly in drought-stressed plants.

DISCUSSION

Drought stress inhibited dry matter production of pistachio plants and Si application significantly improved plant growth only under drought conditions. Plant growth improvement by Si application under drought conditions has been documented in monocot and dicot species including wheat (Gong et al. 2005), rice (Chen et al. 2011) and soybean (Shen et al. 2010) plants. Silicon has been proven to be beneficial for the healthy growth and development of many plant species, particularly Gramineae (Broadley et al. 2012). The beneficial effects of Si are particularly distinct in plants exposed to various environmental stresses. Extensive studies have been performed in order to find possible mechanism(s) for Si-enhanced tolerance of higher plants to abiotic stresses (for review, see Liang et al. 2007, Hajiboland 2012). Rapid progress has been also made in mechanisms for Si uptake and transport in higher plants (Ma and Yamaji 2006).

Chlorophyll fluorescence parameters provide information about PSII photochemistry and reveal possible alterations in leaf photosynthetic activity under stress conditions (Maxwell and Johnson 2000). In this study, it was shown that drought stress declined maximum PSII efficiency ($F_v/F_m$) while increasing non-photochemical quenching ($q_N$). The $F_v/F_m$ is generally considered a parameter very resistant to stress conditions and the decline of $F_v/F_m$ values indicates serious damage to PSII (Maxwell and Johnson 2000). The destruction of the photosynthetic apparatus in drought-stressed plants is mainly the result of photo-inhibition (Cornic 1994). Photo-inhibition has been defined as the inhibition of photosynthesis caused by excessive radiation energy (Krause and Jahns 2004). Photo-inhibition may damage the photosynthetic apparatus, or may cause a slow and reversible reduction of photosynthetic efficiency that leads to a partial loss of capacity to convert radiation energy into net assimilate production. An excess of light energy could be dissipated as heat through $q_N$ (Krause and Jahns 2004) as was observed in drought-stressed plants in this study.

Stomatal closure that limits $CO_2$ availability for dark reactions may be one of the mechanisms for photo-inhibition in drought-stressed leaves in this study. Stomatal control of water loss has been identified as an early event in plant response to water stress (Reddy et al. 2004). On the other hand, photosynthesis can be inhibited under drought conditions even when the stomatal influence is eliminated (leaf disks without epidermis), suggesting that factors other than low $CO_2$ availability affect photosynthesis (Tang et al. 2002). The reduction of $A$ in drought-stressed plants in this study could not only be attributed to the stomatal limitation but may also be explained by inhibited leaf photochemistry as well as metabolic impairment; i.e. the reduction of RuBisCo activity and ATP synthesis (Reddy et al. 2004). Activation of the carbon reduction cycle may be especially sensitive to drought (Reddy et al. 2004). An increased net photosynthetic rate due to Si treatment was observed in the leaves of sorghum (Hattori et al. 2005, Ahmed et al. 2011), wheat (Gong et al. 2005) and soybean (Shen et al. 2010) plants under water stress, which might be associated with an increase in the activity of photosynthetic enzymes such as RuBP carboxylase (Adatia and Besford 1986).

Supplementation of plants with Si slightly or significantly elevated stomatal conductance under both watering regimes. Elevated stomatal conductance particularly in drought-stressed plants may be one of the mechanisms for maintaining dry matter production in plants experiencing water scarcity. It has been demonstrated that drought-tolerant species control stomatal function to allow some carbon fixation during stress, thus improving water use efficiency (Yordanov et al. 2003). On the other hand, providing optimum $CO_2$ concentration for carbon reactions may prevent photo-inhibition, which was clearly reflected in the significantly higher $F_v/F_m$ value in the presence of Si in drought-stressed pistachio plants. Although in Si-treated plants the $F_v/F_m$ value was still lower than in well-watered plants, it was significantly higher than in the drought-stressed plants without Si treatment. The role of Si-mediated increase in the leaf anthocyanins and soluble phenols, which act in protecting chloroplasts against excess light (Goto et al. 2003), could not be excluded. Evidence on the effect of Si treatment on leaf photochemical parameters is very rare and restricted to Gramineae species (Gao et al. 2011).

Although Si-supplemented plants were less conservative in relation to water loss following elevated stomatal conductance, higher RWC implied that Si may help plants to maintain their water balance despite greater water loss, most likely because of higher water uptake. It has been
demonstrated that the application of Si improves the water status of stressed plants (Shen et al. 2010). The application of Si increased root water uptake of sorghum plants without affecting the shoot/root ratio (Hattori et al. 2008, Ahmed et al. 2011, Sonobe et al. 2011). More detailed studies are needed for analysing the effect of Si on root water uptake capacity in pistachio.

Antioxidant enzymes protect plant structural and molecular components from the effects of ROS accumulated during drought stress (Apel and Hirt 2004). Apart from the drought-induced increase in the activity observed for all examined antioxidant enzymes, SOD and CAT activity was significantly higher in drought-stressed plants supplemented with Si compared to plants without Si addition. SOD activity increased upon Si treatment even under well-watered conditions, and further increase under drought conditions may confer plants greater protection against superoxide radicals under water deficiency conditions. The primary scavenger of ROS is SOD, which converts superoxide to hydrogen peroxide and oxygen (Ślesak et al. 2007). The activation of antioxidant enzymes including SOD, CAT, glutathione reductase and dehydroascorbate reductase by Si supplementation has been reported in some plant species (Gong et al. 2005, 2008, Liang et al. 2003, 2007).

The efficiency of antioxidant enzymes in the preservation of membranes against ROS injury was visibly reflected in the stable amount of MDA in drought-stressed plants and is likely another reason for the protective effect of Si on the photochemistry of leaves observed in this study.

Under stress conditions, H_{2}O_{2} in plant tissues can be a precursor of a highly reactive oxygen species (Ślesak et al. 2007). The accumulation of H_{2}O_{2} affects the structure and integrity of plasma membranes by influencing the stress-dependent peroxidation of membrane lipids (Liang et al 2003, 2006). In this research, despite the increasing CAT and APX activity, plants accumulated higher levels of H_{2}O_{2} under drought conditions likely because of enhanced photorespiration.

CONCLUSIONS

1. Under drought conditions, Si supplementation improved plant growth and increased relative water content, maximum quantum yield of PSII and net assimilation rate. However, under well-watered conditions these parameters were not influenced by Si supplementation.

2. Supplementation of plants with Si elevated the stomatal conductance of leaves, which caused an improved CO_{2} fixation capacity under water scarcity. This effect also resulted in providing an optimum CO_{2} concentration for carbon reactions that in turn prevented photo-inhibition. Though there was higher water loss through transpiration in Si-treated plants under drought conditions, increased relative water content implied an enhanced water uptake capacity of roots.

3. Silicon treatment caused an activation of antioxidant enzymes, reflected in the stable amount of lipid peroxidation, while malondialdehyde content dramatically increased in drought-stressed leaves in the absence of Si.
