SINGLE PHASE PWM RECTIFIER IN TRACTION APPLICATION

Ľubomír GRMAN — Martin HRAŠKO
— Jozef KUCHTA — Jozef BUDAY *

This research has been motivated by industrial demand for single phase PWM rectifier in traction application. This paper presents an advanced control structure design for a single phase PWM rectifier. The PWM rectifier is controlled to consume nearly sinusoidal current with power factor nearing to unity. The control structure consists of a DC-link voltage controller and a current controller implemented by a proportional- resonant controller using a fast phase angle and frequency estimator. The estimation algorithm is derived from the weighted least-squares estimation method. The feasibility of the proposed control structure is confirmed by experimental tests performed on designed laboratory prototype.

K e y w o r d s: rectifier, pulse width modulation, control algorithm, resonant control, phase angle estimation, traction application

1 INTRODUCTION

At the beginning of the 1970's, the research and development of electric traction schemes of an electric locomotive with the traction voltage 15 kV/16.7 Hz (Germany, Switzerland, Austria, Sweden, Norway) and 25 kV/50 Hz (France, Spain, *etc*) has been oriented almost exclusively to implementation of a three-phase induction motor as an electric traction motor which had replace a contact DC traction motor with series and separate excitation. Gradually, the traction AC single-phase voltage has been reduced by a traction vehicle transformer with voltage transfer which allows to generate a DC-link voltage for traction frequency converters to supply the three-phase induction traction motor (ITM) with nominal line-to-line voltage (approx. 2–2.2 kV). The marginal power of ITM directed to hundreds kW, today the top locomotives has power about 1.2–1.6 MW. Use this power with four or six ITM in one vehicle requires that from traction line was consumed power with the power factor nearing to unity and minimal distortion of the traction voltage.

After extensive research and verification, it came to the conclusion that impulse rectifier referred to as "four-quadrant converter" is connected to secondary winding of the traction transformer. The power part of converter the most frequently consists the single-phase bridge like other converters makes it possible to transmission of electricity between AC and DC traction system – DC-link of traction frequency converters in both directions. Whereas dimension of the impulse 4Q-converter is pretty simple, the problem appears the control structure in all operating conditions of the vehicle for achieving the power factor nearing to unity. These issues and possible solutions are described in this paper.

In a single phase system, the reference of the line current is a 50 Hz AC signal under the steady state, and the current controller is required to track such an AC reference. There have been several control schemes for an AC tracking controller such as the hysteresis control methods, the predictive control methods, and so on [2], [14]. In this work is used the resonant control approach [4], [7–10] for an AC tracking controller. The proposed control scheme using the PR (Proportional-Resonant) controller that is capable of tracking a sinusoidal line current reference without an additional prediction or an extremely high control gain.

When electrical railway traction crosses over to the power section supplied by another voltage source, the amplitude and/or the phase angle of a source voltage may change in a step manner. In this case, the normal phase angle detector, such as a phase locked loop (PLL) and a lowpass (or notch) filter, typically generates a phase delay, results in a sluggish response, and causes some time critical machine to malfunction. In this work, a source voltage estimator is used based on the weighted least squares estimation (WLSE) method [9]. The proposed estimator provides the phase angle, the frequency, and the magnitude information of the source voltage's fundamental component without a delay.

2 PWM RECTIFIER

The rectifier controlled by pulse width modulation (PWM) consumes current of required shape, which is mostly sinusoidal. It works with a given phase displacement between the consumed current and the supply voltage. The power factor can also be controlled and there are minimal effects on the supply network.

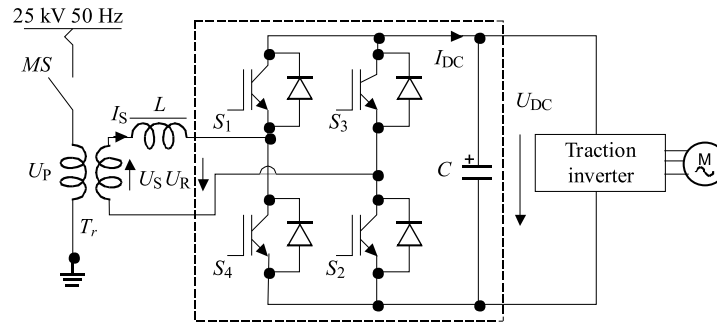

**Fig. 1.** Structure of a single phase PWM rectifier

Fig. 2. Phase diagrams

The main features of PWM rectifiers are [5]:
- bi-directional power flow,
- nearly sinusoidal input current,
- regulation of input power factor to unity,
- low harmonic distortion of line current (THD below 5 %),
- adjustment and stabilization of DC link voltage (or current),
- reduced capacitor (or inductor) size due to the continuous current,
- properly operated under line voltage distortion and line frequency variations.

PWM rectifiers can be divided into two groups according to power circuit connection [1]:

voltage rectifiers (called *boost rectifier* — increases voltage): requires higher voltage on the DC side than the maximum value of the supply voltage. The rectified voltage on the output is smoother than the output voltage of the current type rectifier. They also require a more powerful microprocessor for their control. Output voltage lower than the voltage on input side can be obtained only with increased reactive power consumption.

current rectifiers (called *buck rectifier* — decreases voltage): the maximum value of the supply voltage must be higher than the value of the rectified voltage. The main advantage is that the rectified voltage is regulated from

zero. They are suitable for work with DC loads (DC motors, current inverters).

The PWM single phase rectifier consists of 4 IGBTs connected in full bridge [12] is shown in Fig. 1.

The source power is supplied through a transformer Tr and the input inductance L. The output DC link voltage U_{DC} is filtered by capacitor C and fed into a 3-phase inverter that drives the traction. Supplied voltage U_S and the voltage at the rectifier input U_R are sinusoidal waveforms separated by the input inductance. Therefore the energy flow depends on the angle between these two phases. See the phase diagram in Fig. 2a [1], [5], [11].

The power transferred from the supply to the input terminals of the rectifier is

$$P = \frac{U_S U_R}{X_S} \sin \delta = U_S I_S \cos \phi \qquad (1)$$

where

U_S is RMS value of input supply voltage (V),
U_R RMS value of first harmonics consumed by AC rectifier input (V),
δ phase displacement between phasors U_S and U_R (deg),
X_S input inductor reactance at 50 Hz (Ω),
ϕ power factor.

In order to make the rectified voltage constant the input and output powers must be balanced. Then as the phasor diagram in Fig. 2a shows

$$I_S \cos \phi = U_R \frac{\sin \delta}{X_S}, \qquad (2)$$

$$I_S \sin \phi = \frac{U_S - U_R \cos \delta}{X_S}. \qquad (3)$$

As long as the reactive power consumed is equal to zero the power factor is equal to unity. Therefore (2) and (3) can be adapted to

$$I_S X_S = U_R \sin \delta, \qquad (4)$$
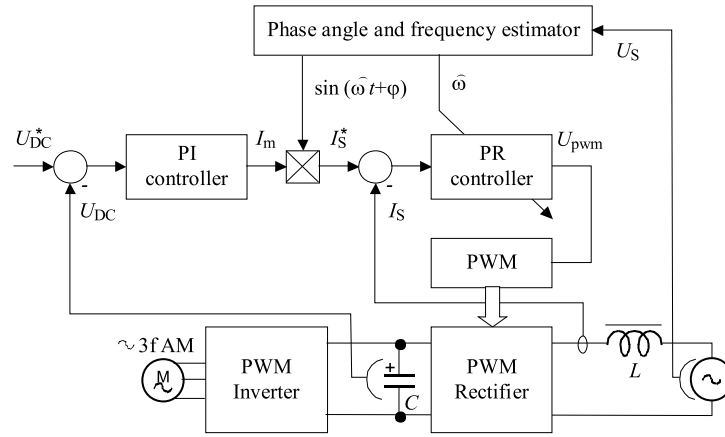

$$U_S = U_R \cos \delta. \qquad (5)$$

Fig. 3. Control structure of a single phase PWM rectifier

The phasor diagrams of the rectifier which works both as a rectifier and as an inverter are shown in Figs. 2b and 2c.

The aim is to control the rectifier in such a way that it consumes harmonical current from the supply network which is in phase with the supply voltage. This can be achieved by controlling the rectifier by pulse width modulation.

3 PROPOSED CONTROL AND ESTIMATION ALGORITHM

3.1 Phase angle and frequency estimation

The phase angle of a source voltage is used to calculate and control the flow of active/reactive power. The phase angle is a critical piece of information for the operation of most power conditioning equipment, such as pulse width modulation AC/DC converter, uninterruptible power supplies (UPS), AC voltage compensators, static VAR compensators (SVC), active harmonic filters etc. In power conditioning equipment, the exact value of a positive sequence is needed to achieve the unity power factor and constant output voltage, whereas the exact value of a negative sequence is needed for unbalance compensation.

A fast phase angle and frequency estimator is presented, which is capable of estimating the phase angle and the frequency of the source voltage even under a highly distorted source voltage condition or sudden amplitude, phase angle, or frequency changing condition. The algorithm is derived from the weighted least squares estimation (WLSE) [8–10].

A single phase voltage U_S is expressed such that

$$U_S(t) = U_m \sin(\omega t + \varphi) = U_d \sin \omega t + U_q \cos \omega t, \quad (6)$$

where

U_m is amplitude of source voltage (V),
ω constant angular frequency (rad/s),
φ phase angle (deg),
   $U_d = U_m \cos \varphi$, $U_q = U_m \sin \varphi$.

By applying the WLSE method to (6), the estimation $\hat{U}_d$ and $\hat{U}_q$ are obtained from U_S such that

$$\hat{\mathbf{x}}(t_i) = \hat{\mathbf{x}}(t_{i-1}) + \mathbf{R}(t_i)\big(U_S(t_i) - \mathbf{H}(t_i)\hat{\mathbf{x}}(t_{i-1})\big),$$
$$i = 1, 2, 3, \dots \quad (7)$$

where $\hat{\mathbf{x}}(t_i) = \big[U_d(t_i) \quad U_q(t_i)\big]^{\top}$,

$\mathbf{H}(t_i) = \big[\sin \omega t_i \quad \cos \omega t_i\big]$,

$\mathbf{R}(t_i) = \mathbf{P}(t_{i-1})\mathbf{H}(t_i)^{\top}\big(1 + \mathbf{H}(t_i)\mathbf{P}(t_{i-1})\mathbf{H}(t_i)^{\top}\big)^{-1}$,

$\mathbf{P}(t_i) = \lambda^{-1}\big(\mathbf{P}(t_{i-1}) - \mathbf{R}(t_i)\mathbf{H}(t_i)\mathbf{P}(t_{i-1})\big)$,

$\lambda \in (0, 1)$ is the forgetting factor,
initial conditions: $\hat{\mathbf{x}}(t_0) = \mathbf{0}$, $\mathbf{P}(t_0) = \gamma \mathbf{I} \in \Re^{2\times 2}$,
$\gamma > 0$ is the initial covariance constant.

The noise immunity of the WLSE estimator can be increased by selecting a larger forgetting factor λ and faster convergence can be achieved by choosing the larger γ.

The phase angles estimation is obtained from $\hat{U}_d$ and $\hat{U}_q$ such that

$$\hat{\varphi}(t_i) = \mathrm{atan}\,2\big(\hat{U}_d(t_i), \hat{U}_q(t_i)\big), \quad i = 1, 2, 3, \dots \quad (8)$$

where $\mathrm{atan}\,2$ is the arc-tangent function.

The frequency information is quite important for phase angle estimation algorithm. The phase angle estimation algorithm can be extended to the estimation of ω, when the frequency varies. When the frequency estimate $\hat{\omega}$ is not equal to the real frequency ω the estimated phase angle φ varies such that

$$\Delta \hat{\varphi} = \hat{\varphi}(t_i) - \hat{\varphi}(t_{i-1}) = (\omega - \hat{\omega})(t_i - t_{i-1}), \quad i = 1, 2, 3, \dots \quad (9)$$

We can recognize that if $\Delta\hat{\varphi} \neq 0$, then there is a frequency estimation error. The basic idea for updating $\hat{\omega}$ is to employ a PI controller (10) so that $\Delta\hat{\varphi}$ is nullified

$$\hat{\omega}(t_i) = \hat{\omega}(t_0) + K_{Pf}e(t_i) + K_{If}\sum_{j=2}^{i} e(t_j),\qquad (10)$$

where $e(t_i) = \hat{\varphi}(t_i) - \hat{\varphi}(t_{i-1})$ is error,

K_{Pf} proportional gain,

K_{If} integral gain.

**Fig. 4.** Time domain response of the PR controller

Fig. 5. Simplified block diagram of the PWM rectifier

The estimated source voltage $\hat{U}_S$ is then obtained as

$$\hat{U}_S(t_i) = \hat{U}_d(t_i)\sin\hat{\omega}t_i + \hat{U}_q(t_i)\cos\hat{\omega}t_i,\quad i = 1, 2, 3, \ldots \tag{11}$$

3.2 Voltage and current controller

The proposed control system consists of the DC-link voltage controller, the current controller, the phase angle estimator and the PWM generator [7], [9], see the structure in Fig. 3.

The DC-link voltage controller is implemented by using a conventional proportional-integral (PI) controller whose output is the amplitude of the current reference I_m and transfer function is given by

$$G_{PI}(s) = K_{Pu} + \frac{K_{Iu}}{s}, \tag{12}$$

where K_{Pu} and K_{uI} are the proportional and the integral control gain, respectively.

The current reference I_s^* is constructed by multiplying the synchronized signal with the source voltage: $I_s^* = I_m\sin(\hat{\omega}t + \varphi)$. The sinusoidal current reference I_s^* is fed into the current controller.

The current controller is constructed based on the proportional-resonant (PR) controller whose transfer function [4] is given by

$$G_{PR}(s) = K_{Pi} + \frac{2K_{Ri}s}{s^2 + \omega^2}, \tag{13}$$

where K_{Pi} and K_{Ri} are the proportional and the resonant control gain, respectively, ω is the fundamental angular frequency of the source current (rad/s).

The time domain response of the resonant controller when $K_{Pi} = 0.5$, $K_{Ri} = 2$, $f = 50$ Hz with sinusoidal input $\sin\omega t$ is shown in Fig. 4.

It can be seen from Fig. 4 that the gain of the transfer function (13) is infinity at ω, the output is in phase with the input signal, but the amplitude is amplified with time. With the resonant control method, one can track the high frequency sinusoidal current reference without increasing the switching frequency nor adopting an extremely large control gain.

For a proper operation of PWM rectifier a minimum DC-link voltage is required [1], [3], [5]. Generally, it can be determined by the maximum value of the supply voltage U_S that is

$$U_{DC\min} > U_{S\max} \quad \text{or} \quad U_{DC\min} > \sqrt{2}U_{S(RMS)}. \tag{14}$$

If this condition is not fulfilled, the full control of the input current is not possible. Defining the natural DC-link voltage value (as it is possible to obtain in case of not operating transistors) the freewheeling diodes constitute a standard diode bridge. Typically, the reference value for the controlled DC-link voltage should be chosen about 10 % above the natural DC-link voltage. The unity power factor required for PWM rectifier operation can be obtained in case of

$$U_R^2 = U_S^2 + U_L^2. \tag{15}$$

The voltage drop across the inductor U_L depends on reactance L of the inductor at the input frequency and on the input current I_S. The magnitude of the switching voltage vectors depends on the DC-link voltage level [5].

4 EXPERIMENTAL RESULTS

The control structure of a single phase PWM rectifier has been confirmed by experimental tests performed on designed laboratory prototype. Block diagram of the PWM rectifier control system is shown in Fig. 5. The power part is realized by four IGBT transistors and the
Fig. 6. Transient responses when DC-link voltage changes gradually with no-load; a) input voltage and current, b) DC-link voltage, power factor and frequency

Fig. 7. Transient responses (PWM rectifier and inverter): no-load AM; a) input voltage and current, b) DC-link voltage, power factor and frequency

digital signal processor TMS320F28335 (Texas Instruments) was chosen as controller and for computing WLSE algorithm.

In order to keep proper function of control algorithm, it is necessary to synchronize the control structure with power grid voltage curve. When supposing purely sinusoidal voltage curve, we only need to know the moments when the voltage curve crosses the zero axes (moments of polarity change) and the voltage polarity in every half-period. The easiest way to follow this condition is to convert sinusoidal curve (power grid voltage) into the square shape with logical levels of 0 and 3 V, otherwise log. 0 and log. 1 as well. Log. 0 corresponds to negative half-wave, log. 1 to positive. Signal edges indicate the zero crossings. The DSP processor these zero crossing by means of ex-

ternal interrupt. The polarity is evaluated from the zero crossing direction — rising or falling edge [6].

Experiments were performed with the parameters of controllers given in Tab. 1. The switching frequency was set to be 5 kHz and the parameters of the phase angle estimator were selected such that $\lambda = 0.9999$ and $\gamma = 0.02$.

Table 1. Parameter list of the controllers

| Parameters of the controllers:					
frequency		voltage		current	
K_{Pf}	20	K_{Pu}	1.15	K_{Pi}	0.4
K_{If}	1000	K_{Iu}	0.008	K_{Ri}	0.012

Fig. 8. Transient responses (PWM rectifier and inverter): short-circuit AM in $t_s = 0.2$ s; a) input voltage and current, b) DC-link voltage, power factor and frequency

Fig. 9. Transient responses (Transient responses (PWM rectifier and inverter): load on AM; a) input voltage and current, b) DC-link voltage, power factor and frequency

The conditions for test were: $U_{Sm} = 145$ V, $U_{DC} = 280$ V, the input inductor $L = 35$ mH, the DC link capacitor $C = 3000\,\mu$F. The parameters of asynchronous motor were: $P_n = 1.5$ kW, $U_n = 230$ V/400 V, $f = 50$ Hz, $n = 705$ rpm, $M_m = 20$ Nm and number of poles $p = 8$.

The experimental tests of a single phase PWM rectifier has been performed by asynchronous motor (AM) with no-load, short-circuit and load on. The asynchronous motor has been loaded on by the synchronous linear motor with permanent magnets (SMPM). The results of experimental tests are shown in the following figures.

Figure 6 shows the experimental results of transient responses (PWM rectifier) when DC-link voltage changes gradually and no-load is attached. The input current surge is reduced by the ramp of reference value of DC-link voltage. The required value U_{DC} is reached in time

0.25 s. The steady-state value of power factor is 0.995 and the average value of frequency is 49.74 Hz. The results of transient responses (PWM rectifier and PWM inverter) when AM has no-load is shown in Fig. 7. In this case the value of power factor is 0.992 and the average value of frequency is 49.62 Hz. Figure 8 shows the experimental results of transient responses (PWM rectifier and PWM inverter) when short-circuit is applied on the AM in time $t_s = 0.2$ s. Drop of DC-link voltage is about -0.8% (248 V) from reference value (250 V). The steady-state value of power factor is 0.992 and the average value of frequency is 49.77 Hz. The results of transient responses when AM is loaded on moment 4 Nm by SMPM is shown in Fig. 9. Drop of DC-link voltage is about -10.4% (251 V) from reference value (280 V) and the steady-state value of power factor is 0.995.

5 CONCLUSION

This paper presented an advanced control structure design for a single phase PWM rectifier. The control structure consists of a proportional-resonant controller using a fast phase angle and frequency estimator. The estimation algorithm is derived from the weighted least-squares estimation method.

The PWM rectifier can perform well in many applications, for example as an active filter or as an input rectifier for an indirect frequency converter. This application is useful mainly in traction, where the AC voltage from the trolley wire is first rectified, and the traction inverters and also other auxiliary converters are fed from the output of the rectifier. A traction vehicle equipped with a PWM rectifier does not consume reactive power, will not load the supply network with harmonics and can recuperate. The proposed control structure is confirmed by experimental tests performed on designed laboratory prototype.
