ABSTRACT
Liver cirrhosis is a major risk factor for increased mortality and morbidity in patients undergoing non-hepatic surgery with overall mortality rates as high as 45–50%. However, cirrhotic patients are often in need of surgical procedures including urological surgeries like cystectomies for muscle invasive bladder cancer. Data on the prognosis of these patients undergoing cystectomy for bladder cancer are scarce in the literature. In the present case-study, we describe the outcomes of 3 patients with liver cirrhosis who underwent radical cystectomy for muscle invasive bladder cancer. To the best of our knowledge, this is the first study reporting on this kind of urological surgery in patients with liver cirrhosis. Accordingly, we provide a review in the literature on prognosis and factors influencing the survival of cirrhotic patients who undergo surgical procedures.

Key words: liver cirrhosis, Child-Pugh score, MELD score, urologic surgery, non-hepatic surgery, bladder cancer

INTRODUCTION
Liver cirrhosis is a major health problem, as according to World Health Organization (WHO), it accounts for 1.8% of all deaths in the European population. Indeed, liver cirrhosis is responsible for approximately 170,000 deaths/year in Europe including almost 50,000 deaths/year due to hepatocellular carcinoma.[¹,²] However, apart from hepatocellular carcinoma, extra-hepatic malignancies also seem to develop more frequently and at an earlier age in patients with cirrhosis.[³–⁵] In this context, it is well known that cirrhotic patients carry an increased risk of several types of cancers namely, cancer of the lung, larynx, buccal cavity, pharynx, pancreas, urinary bladder, and kidney, which are usually associated with common habits of the patients like tobacco and alcohol abuse.[⁶–⁹]

The survival of non-hepatic cancer patients with accompanied liver cirrhosis varies according to the severity of liver dysfunction.[¹⁰,¹¹] In more detail, the prognosis of patients with advanced cirrhosis (decompensated, Child-Pugh C cirrhosis) and concomitant extra-hepatic cancer depends mostly on the liver disease, while patients with compensated liver disease rather die from tumor-related complications. The latter patients are good candidates for specific anticancer treatment, as they might have a clinically relevant benefit in terms of survival.[¹²]

On the other hand, surgical treatment is frequently indicated in patients with cancer especially at early tumor stages, being in many cases, the only curative treatment option. However, in spite of the significant advances in surgical and intensive care management of the patients, liver cirrhosis is considered a major risk factor carrying an increased morbidity and mortality in cirrhotic patients undergoing any kind of surgery, as they can often decompensate because of both anesthesia and surgery.[¹²–¹⁵] Diverse scores and indexes have been used for predicting the outcome of patients preoperatively, among which the American Society of Anesthesiologists (ASA) score and the age-adjusted Charlson Comorbidity...
Radical cystectomy accompanied by pelvic lymphadenectomy remains the most effective and widely used surgical intervention for muscle invasive bladder cancer (MIBC) and is considered the treatment of choice for these patients.\(^{[20]}\) This operation is still associated with a rate of complications of about 27% and mortality of 0.8%.\(^{[21]}\) Complications are generally due to the operation itself and to the host. Actually, the complications associated with the procedure are related to the extent of surgical extirpation and the need of intestinal reconstruction, whereas those related to the patient characteristics are dependent on the patient’s age and the presence of the underlying comorbidities.\(^{[22]}\) To date, there are very scarce data on the safety and outcome of radical cystectomy for MIBC in patients with liver cirrhosis. Therefore, we report herein the outcome of 3 patients with liver cirrhosis who underwent open radical cystectomy for MIBC and discuss risk factors of poor survival in these patients undergoing surgery.

**Case 1**
A 63-year-old Caucasian man, heavy smoker with known liver cirrhosis due to hepatitis B was presented in our department with intermittent macroscopic hematuria initiated 4 years ago. The abdominal CT revealed an exophytic bladder mass and transurethral resection biopsy revealed muscle invasive high grade urothelial carcinoma. CT of the thorax was normal. During the preoperational work-up the patient was classified as Child–Pugh B, with a MELD score of 12, ASA score III, aCCI 5 and performance status (PS) 0 (Table 1). The preoperative laboratory tests are shown in Table 2. Radical cystoprostatectomy with extended lymph node dissection and a cutaneous ureterostomy was performed under general anesthesia. The total operative time was 165 min with intraoperative transfusion of 1 unit of red cells. During the postoperative period, ascites developed; and during the 11\(^{th}\) postoperative day, abdominal wound dehiscence with evisceration occurred, which led to a surgical correction but the patient soon after developed fever and secondary bacterial peritonitis. Despite intense antibiotic therapy, the patient finally passed away on the 16\(^{th}\) day due to septicemia, hepatorenal syndrome and hepatic encephalopathy. The biopsy showed pT2N0M0 muscle invasive urothelial carcinoma.

**Case 2**
A 72-year-old Caucasian man, heavy smoker with history of alcoholism, current hepatitis B virus infection and right nephroureterectomy due to upper urinary tract urothelial tumor was presented in our clinic with macroscopic hematuria. The abdominal CT revealed bladder mass and following transurethral resection biopsy a muscle invasive, high grade, urothelial cancer was found. Preoperatively, liver cirrhosis was classified as Child-Pugh A, with MELD score 10, while the ASA score was III, the aCCI 8 and PS 0 (Table 1). CT of thorax was normal. The preoperative laboratory work-up is shown in Table 2. Radical cystoprostatectomy with extended lymphadenectomy and ileal conduit (Bricker) diversion was performed. The operation lasted 231 minutes and there were no intra-operative complications while no blood transfusion was required. Postoperative period was uneventful except for leaking ascites. Patient was discharged at the 10\(^{th}\) postoperative day with antibiotic coverage. Biopsy specimen revealed a muscle invasive bladder pT2N0M0. During follow-up the patient was stable, without recurrence of ascites or development of other complications due to cirrhosis. However, in 9\(^{th}\) month of follow-up, he developed bone metastatic disease, for which he received palliative radiotherapy. The patient died 36 months after surgery due to disseminated metastatic disease.

**Case 3**
A 69-year-old Caucasian man, heavy smoker, was admitted to our hospital with severe macroscopic hematuria. The patient had a 10 years history of cirrhosis due to hepatitis B. Urinary bladder ultrasound revealed an exophytic bladder tumor, abdominal and lung CT scans were negative for metastasis, while the transurethral resection biopsy revealed a muscle invasive, high grade, urothelial carcinoma. Preoperatively, the patient was classified as Child-Pugh

CTP: Child-Pugh classification; MELD: model for end-stage liver disease; ASA: American Society of Anesthesiologists physical status classification; CCI: Charlson comorbidity index.
A, with MELD score 6, ASA score III, aaCCI5 and PS 0 (Table 1), while the laboratory work-up is shown in Table 2. Radical cysto-prostatectomy with extended lymph node dissection and ileal conduit (Bricker) was performed. The operative time was 255 minutes and no major intra-operative complications occurred. After surgery, the patient was transferred directly to the general urology floor with no need for the intensive care unit. During the postoperative period, no complications occurred; the drain was removed on the 6th post-operational day and patient was discharged on the 10th post-operative day. Pathology examination showed a pT3aN0M0 bladder tumor. The patient is still alive 24 months post-surgery, with no evidence of disease on imaging, while his liver disease is stable and well compensated.

**DISCUSSION**

In the present case-study, we describe the outcomes of 3 patients with liver cirrhosis who underwent radical cystectomy for muscle invasive bladder cancer. To the best of our knowledge, this is the first study reporting on this kind of severe urological surgery in patients with liver cirrhosis. It is well known that non-hepatic surgery in cirrhotic patients is challenging with a high mortality rate. Studies reporting morbidity and outcome in patients with cirrhosis undergoing non-hepatic surgery have shown variable results with in-hospital mortality rates ranging from 8.3% to 25% compared to 1.1% in non-cirrhotic patients.[13,23] The severity of liver disease, and secondarily, the nature of surgical procedure seem to be the most important factors of postoperative outcome.[24]

In cirrhotics, the hemodynamic impairment (increased cardiac output, splanchnic vasodilatation and decreased systemic vascular resistance) because of the loss of hepatic reserve usually result in inappropriate responses to surgical stress. Furthermore, these patients are at an increased risk of bleeding, infection, postoperative hepatic decompensation, including hepatic coma or death. In general, elective surgery is well tolerated in patients with Child-Pugh A cirrhosis, while it is permissible with good preoperative evaluation in patients with Child-Pugh B and is contraindicated in patients with Child-Pugh C cirrhosis.[13,23] In particular, mortality rates after major abdominal surgery were 10% for Child-Pugh A, 30% for Child-Pugh B and 76%–82% for Child-Pugh C cirrhosis.[24] Similarly, MELD score also predicts mortality after surgery and seems to correlate better with outcome. Thus, a MELD score 0–11 is associated with 5v10% 90-day mortality, a 12–25 score with 25–54% and scores above 26 with 90% postoperative mortality rate.[25] Teh et al.[25] concluded that the most important predictors of mortality are severity of liver disease as reflected by the MELD score, age.

*According to Cocroft-Gault formula, **AST < 40 UI/L, ALT < 35 UI/L, ALP < 120 UI/L, γ-GT < 40 UI/L.

Hct: hematocrit; Hg: hemoglobin; WBC: white blood cell; AST: aspartate aminotransferase; ALT: alanine aminotransferase; γ-GT: gamma glutamyl transferase; ALP: alkaline phosphatase; LDH: lactate dehydrogenase; INR: international normalized ratio; aPTT: activated partial thromboplastin time.
and comorbidities as determined by the ASA physical status classification. Indeed, in our study, the 2 patients with Child-Pugh A and low MELD scores did not have major peri- and post-operative complications, while the patient with Child-Pugh B and a higher MELD score died due to surgical complications, but also major disease decompensation (hepatorenal syndrome and hepatic encephalopathy).

On the other hand, the kind of surgical procedure is the second crucial determinant of postoperative outcome. The morbidity and mortality risks are the highest in patients undergoing cardiac surgery (up to 31% perioperative mortality) and open abdominal surgeries. Abdominal surgery in particular, is more often complicated by hepatic ischemia, while the risk of intra-operative bleeding is increased due to the presence of portal hypertension. Moreover, perfusion may be impaired from anesthesia, which may also reduce the hepatic blood flow and decrease oxygen uptake by the liver.

Radical cystectomy with extended lymphadenectomy is considered the standard treatment of muscle invasive bladder cancer with an overall 5-year survival up to 70% for pT2 disease. However, the complications of the procedure, due to surgery itself as well as the urinary diversion, remain high. Lughezzani et al. in a large population-based competing-risks analysis of the survival of patients treated with radical cystectomy found that even after adjusting for bladder cancer pathologic stage, cancer-specific mortality was higher in older individuals than in younger ones. Our patients were > 60 years old but < 80 years with a 5 year cancer-specific mortality rate of around 30% and all had PS 0, which is correlated with an excellent overall survival after radical cystectomy.

According to the aaCCI, which is recommended by the European Association of Urology guidelines for assessing patients with muscle invasive bladder cancer before therapeutic decision making, the two patients with aaCCI 5 had a probability of survival of 0.8 at 2 years and the third with aaCCI 8 had a probability of survival of 0.35 at 2 years. Under this context, Abdollah et al. had a probability of survival of 0.35 at 2 years. Under this context, Abdollah and the third with aaCCI 8 had a probability of survival of 0.8 at 2 years before therapeutic decision making, the two patients with aaCCI 5 had a probability of survival of 0.8 at 2 years.

In conclusion, radical cystectomy in cirrhotic patients is challenging but feasible. As in any other surgical procedure, the degree of liver impairment seems to significantly influence postoperative mortality in cirrhotic patients. For this reason, patients should be evaluated preoperatively and carefully classified according to their cirrhosis stage, while other classifications such as aaCCI, probably predicts better the cancer-related mortality. However, further multicenter studies are needed in order to make clear suggestions for better therapeutic decision-making in this rare group of patients. We are currently undertaking such studies. Nevertheless, the optimal management of cirrhotic patients with bladder cancer requires deep knowledge of both diseases and an interdisciplinary approach.
