ABSTRACT

OBJECTIVE. To evaluate the importance of computerized dynamic posturography in vestibular rehabilitation of patients with unilateral peripheral vestibular deficiency syndrome.

MATERIAL AND METHODS. The study was conducted on a group of 30 patients (33-78 years; mean age (± SD) = 55.8 ± 12.12) diagnosed with unilateral peripheral vestibular deficiency syndrome, which benefited from VR on a posturography platform. Assessment of the patients was made using the Sensory Organization Test before and after eight sessions of rehabilitation. We analyzed the results obtained with eyes open (EO) and eyes closed (EC) on static and foam platform. The following variables were evaluated: Romberg coefficient, statokinesigram (SKG), maximum amplitude of the degree of deviation in anterior/posterior and medial/lateral planes, SKG and the time interval of the game rehabilitation program.

RESULTS. The statistical analysis of the data revealed a strong correlation (p<0.05) for the studied parameters, especially when the test was performed with the eyes closed on foam platform. The analysis of the Romberg coefficient did not show statistically significant results (p>0.05) and the measured values were outside the range of normality even at the end of the rehabilitation program. SKG and the time interval reference of the game showed significant improvement of the parameters (p<0.05); at the end of the rehabilitation sessions, 93.33% of the patients showed full recovery of their deficit.

CONCLUSION. Computerized dynamic posturography has a particularly important role in the evaluation, monitoring and rehabilitation of the patients with peripheral vestibular deficiency.

KEYWORDS: computerized dynamic posturography, vestibular rehabilitation, peripheral vestibular disorders, foam platform

INTRODUCTION

Computerized dynamic posturography (CDP) is a quantitative method which evaluates the ability of the human body to maintain balance in upright position in various testing conditions that replicate real-life situations².

Body position, in relation to gravity and environmental landmarks, is perceived by various information coming from the proprioceptive, vestibular and visual systems. The visual system is important in maintaining balance when the environment is in motion². For maintaining balance, the patient must coordinate eye movements to obtain a stable image of the environment on the retina. Maintaining balance during movement is achieved with the help of the proprioceptive system that provides information from the proprioceptive receptors in the striated muscles of the legs and neck⁵. The role of the vestibular system becomes particularly important when the first two systems do not work properly⁴. In addition to assessing and identifying patients with peripheral vestibular deficit, CDP can also be used in vestibular rehabilitation (VR) programs⁵. VR helps regaining postural control and elim-
inates the risks of falls in patients with vestibular deficiency.

The role of VR program is to interconnect the information received from the somatosensory and visual system with those provided by the vestibular system6-8.

Our study aimed to assess the role of CDP in the VR of patients suffering from peripheral vestibular syndrome.

MATERIAL AND METHODS

Patients
We conducted a prospective cohort study during January 2012 - December 2014 that analyzed 30 patients with unilateral peripheral vestibular deficiency syndrome who received vestibular rehabilitation using platform posturography9. All patients included in the study signed an informed consent form to participate in the study. All patients have completed the vestibular rehabilitation program on platform posturography.

Inclusion criteria: patients who have never benefited from VR on posturography platform and patients with normal neurological exam. We considered also the patients with benign paroxysmal positional vertigo (BPPV) that previously benefited from canalith repositioning procedures, but still showed unsteadiness evidenced by posturography.

We excluded the patients who refused participation in the study, those with associated neurological disorders (e.g. Dementia, Parkinson’s disease), psychiatric disorders, visual disturbances; patients treated with neuroleptics, sedatives, antiepileptics, antidepressants, drug or alcohol abuse, patients with severe orthopaedic dysfunction and arthrosis of the ankle, hip and knee.

Study Protocol
In this study we used the Posturographic Synapsys System (version 3.0, SYNAPSYS, Marseille, France). All the patients were evaluated using the Sensory Organization Test that monitors the three sensory systems involved in maintaining balance (proprioceptive, visual and vestibular). The evaluation was conducted at the onset and at the end of eight sessions of VR. In our study, we considered the results obtained from patients that were tested with eyes open (EO) and eyes closed (EC) on foam platform. Each test consisted of two trials that lasted 20 seconds each and the VR program consisted in 8 sessions (2 sessions/week)10,11. The VR program consisted in rehabilitation games included in the software used by the posturographic system. Each session began with a test reference which helped monitor the patient’s evolution throughout the rehabilitation. The reference game was the same for each session and patient included in the study. In the rehabilitation session we included games from four groups: Stabilization, Weight shift, Weight bearing and Postural control.

Statistical analysis
The collected data was analyzed using the software Stata IC 11 (StataCorp. 2009. Stata: Release 11 Statistical Software. College Station, TX, USA). The data was expressed as a percentage, frequency, mean, standard deviation, depending on the situation. The T test (Student) was used for the evaluation of quantitative differences in the calculation of media. The level of statistical significance was set at 0.05.

The normal values of parameters followed during the study: Romberg coefficient, statokinesigram (SKG), maximum amplitude of the degree of deviation in anterior/posterior (AP) and medial/lateral (ML) planes were obtained from the posturographic system software (Table 1).

The normal values used for the Romberg coefficient were between 85-241.

To evaluate the therapeutic success of vestibular rehabilitation on platform posturography, we based our observations on the following ranges of values for each parameter obtained on foam platform after the 8 sessions of VR (Table 2).

These ranges of values were used to be able to classify patients included in the study, according to their performance in two groups: stationary and improved. The creation of these groups was necessary to assess the therapeutic success of vestibular rehabilitation on platform posturography in patients with unilateral peripheral vestibular deficiency syndrome.

RESULTS

The clinical study was conducted on a group of 30 patients with unilateral peripheral vestibular deficiency syndrome, including 14 women (46.67%) and 16 men (53.33%); 13 cases originated from rural areas (43.33%) and 17 cases from urban areas (56.67%). The mean age was 55.8 years ±12.12 SD (age between 33 and 78 years).

We analysed the associated risk factors and we encountered 10 patients with cervical spondylosis (33.33%), 8 cases with systemic hypertension (26.67%), 8 cases with dyslipidemia (26.67%), 5 cases (16.67%) with carotid atheromatosis and 5 cases (16.67%) with diabetes mellitus. Vestibular rehabilitation therapy (VR) on posturography platform was performed to patients with unilateral peripheral vestibular deficiency syndrome (vestibular neuronitis, Meniere’s syndrome) and BPPV patients presenting with postural instability (previously benefited from canalith repositioning procedures). In this study we did not include patients diagnosed with acoustic neurinoma.

We recorded statistically significant differences between the results obtained on platform posturography before (RQ1, SKG1, AP1, ML1) and after (RQ2, SKG2, AP2, ML2) vestibular rehabilitation, especially with EO and EC on foam platform (p<0.05), as one can see in Table 4.

Statistical analysis of parameters with EO and EC on foam platform before and after vestibular rehabilitation on platform posturography

In EO condition, there was a significant decrease of the statokinesigram after VR (p<0.05) from an average of 923.61±805.86 mm before VR to an average of 552.366±456.885 after VR. The average difference was 371.2 (p=0.0002; Student t-test; 95%CI varies between 195.55 and 545.92). After the rehabilitation, we observed a decrease in balance on AP plan (p<0.05) from an average of 37.53±13.87 mm to an average of 29.40±7.97 mm. The average difference was equal to 8.13 (p=0.0081; Student t-test; 95%CI = 2.2 - 13.9). Regarding balance on ML plan after VR, the results show a significant decrease (p<0.05) from an average of 43.27±22.62 mm to 17.92mm±31.09 mm after the eight VR sessions. The average difference was 12.18 (p<0.0001; Student t-test; 95%CI = 7.6-16.67).

* For the study we selected BPPV patients with postural instability after canalith repositioning procedure. Dix-Hallpike maneuver used for the posterior semicircular canals and specific manoeuvres for the lateral semicircular canals were negative for these patients.
In EC condition, there was a significant decrease of the statokinesigram after RV (p<0.05) from an average of 2443.43±947.90 mm before VR to an average of 1142.99±641.53 mm after VR. The average difference was of 1300.44 (p<0.0001; Student t-test; 95% CI between 1018.5 and 1582.3). After VR, we observed a decrease in balance on AP plan (p<0.05) from the average value of 71.52±20.69 mm before to an average of 47.40±9.42 mm. The average difference is 24.11 (p<0.0001; Student t-test; 95% CI 16.8 to 31.3 is from).

Regarding ML balance, results after VR showed a significant decrease (p<0.05) from 67.88±21.83 mm to an average of 38.65±13.99 mm; the average difference of 29.23 (p<0.0001; Student t-test; 95% CI was between 23 and 35.4).

**Statistical analysis of statokinesigram (cm2) and time (seconds) of the reference game before and after the vestibular rehabilitation process**

In terms of the SKG obtained in the reference game.
after VR, there was a significant decrease (p<0.05) from an average of 15.06±3.47 cm² before VR to an average of 15.14±1.55 s. The average difference was equal to 15.97 (p<0.0001; Student t-test; 95% CI = 14.57-17.37).

In both cases there was a significant decrease in parameters values after VR (p<0.05).

Statistical analysis of the Romberg coefficient before and after vestibular rehabilitation on platform posturography

Comparing the final mean values to the initial mean values of the Romberg coefficient (RQ2 versus RQ1), we found a mean difference of 4.066 (p=0.8691; Student t-test; 95% CI ranging between 54 and 49.94). Given that p>0.05, the difference between the two values is not statistically significant.

The final results showed that of the 30 patients with unilateral peripheral vestibular deficiency 28 (93.33%) were fully rehabilitated, 1 patient showed improvement (3.33%) and 1 patient was stationary (3.33%). It should be noted that changes were evident since the end of the first session.

DISCUSSIONS

Computerized dynamic posturography (CDP) is a technique commonly used to quantify postural control. In addition to assessing and identifying patients with vestibular deficit, CDP can be used during VR sessions. Although this technique is commonly used, there are few studies that demonstrate its effectiveness in using the platform posturography for VR of patients with unilateral peripheral vestibular deficiency.

Nardone has highlighted the effectiveness of vestibular rehabilitation on the platform in an important study conducted in 2010 on 33 patients with peripheral vestibular deficit. Furthermore, studies in patients with central vestibular deficit showed that vestibular rehabilitation with platform posturography can significantly decrease the risk of falls, improve postural stability and increase the quality of life of these patients.

Our results showed that patients had improved postural control after using the VR on posturography platform. On average, patients with peripheral vestibular disease with unilateral deficit, showed statistically significant changes (p<0.05) in the values of the six parameters studied. The statokinesigram and the time of the reference game before and after VR improved significantly (p<0.0001), proving the therapeutic success of VR in the patients included in our study. At the end of the rehabilitation program, the results were more than satisfactory; 93.33% of cases achieved full recovery of the vestibular function.

Even though the recovery of the vestibular function depends on the severity of vestibular damage, the studies show that controlled and monitored rehabilitation programs can lead to a high level of recovery.

CONCLUSIONS

CDP allows evaluation and rehabilitation of vestibular function by assessing the overall balance and identification of the systems used by the patient to maintain posture. Using platform posturography in vestibular rehabilitation programs allows multisensory rehabilitation by using the interconnection between visual, vestibular and proprioceptive information.

Given the encouraging results of the present study, we can say that the monitored parameters in this article may be useful for creating guidelines for vestibular rehabilitation programs in the future.
