ABSTRACT

Isoform 2 of calsequestrin (CSQ2) is the main calcium-binding protein of the sarcoplasmic reticulum (SR) and is expressed in both cardiac and skeletal muscle. CSQ2 acts as an SR calcium (Ca\textsuperscript{2+}) sensor and regulates SR Ca\textsuperscript{2+} release via interactions with triadin, junctin, and the ryanodine receptor. Various mutations of the csq2 gene lead to altered Ca\textsuperscript{2+} release and contractile dysfunction and contribute to the development of arrhythmias and sudden cardiac death in young individuals affected by CPVT. Transgenic mice carrying one of the identified CSQ2 point mutations (R33Q) associated with CPVT were developed, and a drastic reduction in the mutated protein was observed. Following a biomolecular approach, several analyses were performed using different antibody treatments to identify when the reduction of CSQ2 begins, to unveil the mechanism involved in the reduction of CSQ2 and to verify whether other proteins are affected by the presence of the mutated protein. The results of this study showed that mutated CSQ2 levels decreased soon after birth, in conjunction with decreased levels of other important junctional SR proteins, including triadin (TD). The up-regulation of proteins associated with the unfolded protein response (UPR) was also observed, and the ATF6-dependent pathway was activated by the UPR. The presence of the R33Q mutation induced the decrease of CSQ2 via UPR activation and subsequent proteasomal degradation.

Keywords: Calsequestrin, CPVT, ERAD, UPR, Triadin, Chaperones.

SAŽETAK

Izoforma 2 kalsekvestrina (CSQ2) je glavni kalcijum-vezujući protein sarkoplazmatskog retikuluma (SR) i nalazi se kao u srčanom tako i u skeletnom mišiću. CSQ2 deluje kao kalcijumski receptor koji reguliše oslobađanje Ca\textsuperscript{2+} jona iz SR, putem interakcije sa triadinom, junktinom i rianodinskim receptorom. Različite mutacije csq2 gena mogu da izazovu poremećaje u oslobađanju Ca\textsuperscript{2+} i time kontraktilne funkcije, čime doprinose razvoju aritmija i iznenadnoj smrti mladih osoba koja boluju od kateholaminerške polimorfne ventrikularne tahikardije (CPVT). Razvojem transgenetskih miševa sa CSQ2 point mutacijom (R33Q) i CPVT-om, primenjen je drastičan pad nivoa mutiranog proteina. Prateći biomolekularni pristup, nekoliko analiza je izvedeno, koristeći tretman različitim antitelima, sa ciljem da se otkrije kada počinje smanjenje nivoa CSQ2, raspoređivanje mehanizama uključen u redukciju CSQ2 i ispita da li prisustvo mutiranih proteina učiće i na druge proteine. Rezultati ove studije su pokazali da se nivoi mutiranih CSQ2 smanjuju ubrzo nakon rodjenja, što je udržano sa smanjenim nivom ostalih značajnih proteina SR, uključujući triadin (TD). Takođe je primeteno da odgovor nesavijenih proteina može biti povezan sa ushodnom regulacijom proteina i aktivacijom ATF-6 zavisnog signalnog puta. Prisustvo R33Q mutacije je izazvalo smanjenje nivoa CSQ2 putem aktivacije odgovora nesavijenih proteina i posledične proteozomalne degradacije.

INTRODUCTION

Sudden cardiac death causes approximately 300,000 deaths each year in Europe and the U.S.A.; ventricular fibrillation is the underlying mechanism of most diseases that lead to sudden cardiac death. The identification of mechanisms causing life-threatening arrhythmias is a major priority in the biomedical field (1, 2). Given the crucial role of Ca\textsuperscript{2+} in the generation of focal arrhythmias, the mechanisms responsible for Ca\textsuperscript{2+} homeostasis in the SR of cardiomyocytes are of great importance in cardiac pathophysiology. The discovery of SR proteins, such as ryanodine receptor (RyR) and CSQ, that play key roles in the mechanisms behind underlying inherited arrhythmia syndromes such as CPVT emphasises the link between changes in intracellular Ca\textsuperscript{2+} homeostasis and arrhythmogenesis (3, 4). CPVT occurs at a young age as a result of exercise or emotional stress, is characterised by recurrent syncope, convulsions, and cardiovascular collapse and can lead to sudden death (4). Homozygous CSQ2 mutations (5) explain 3% of all CPVT cases, while approximately 50% of patients have mutations in RyR2 (6). Song and colleagues (7) have demonstrated the existence of common pathophysiological mechanisms caused by alterations in RyR2 and/or CSQ2 that relate to CPVT.

To close the gap between experimental and clinical data, it is extremely important to develop experimental animal models that phenotypically copy the clinical disease. This "challenge" is particularly demanding in arrhythmogenic diseases because of the large differences between humans and mice in ion channel profiles and action potential durations. CPVT has proven to be an exception in comparison with other hereditary diseases, represented by transgenic mice models that phenotypically copy the clinical disease. This is particularly challenging in CPVT because of the large differences between humans and mice in ion channel profiles and action potential durations. Thyroid-stimulating hormone (TSH) receptor knockout mice have been crossed to CPVT mice to create transgenic mice expressing defective proteins, which show altered abilities to bind Ca\textsuperscript{2+} and/or to perform their proper function (9). All experimental evidence has implicated mechanisms of post-transcriptional regulation. Among the possible mechanisms involved in this regulation is endoplasmic reticulum (ER)-associated protein degradation (ERAD), which is responsible for the degradation of proteins synthesised at the ER lumen via the proteasome following activation of an ER stress response pathway.

Various factors can activate an ER stress response pathway. One such factor, the presence of incorrectly folded proteins, activates the unfolded protein response (UPR). To reach a possible explanation for the drastic reduction of CSQ2-R33Q in 8-week-old adult mice (9), the first objective was to determine at what age the CASQ2 reduction began. The other objectives were to determine whether any other proteins were affected by the reduced levels of CSQ2 and to reveal the mechanisms involved in the reduction of CSQ2-R33Q.

MATERIALS AND METHODS

Molecular analyses were performed on total heart homogenates of 4 wt/wt and 4 knock-in CSQ2-R33Q/R33Q mice, respectively. All experimental protocols were approved by the Institutional Ethical Committees of the Universities of Padova and Chieti. Mice were kept in accredited animal facilities and sacrificed by anaesthetic euthanasia. Four hearts were used for each genotype, and only male mice were selected for the analyses. The samples were homogenised, and the corresponding proteins were quantified using the Lowry biochemical method.

Western Blotting was used for protein level determination. For each sample, 15–50 μg of protein was loaded onto 7.5–10% SDS-polyacrylamide gels, depending on the protein being investigated. The following dilutions and primary antibodies were used: polyclonal anti-CASQ1/CASQ2 (1:1,000), monoclonal anti-TR (1:1,000), polyclonal anti-BiP (GRP78) (1:500), and polyclonal anti-CRT (1:1,000), all from Affinity Bioreagents (Affinity Bioreagents, Golden, CO); polyclonal anti-GRP94 (1:1,000) from Santa Cruz (Santa Cruz Biotechnology, Santa Cruz, CA); and monoclonal anti-ATF6 from Thermo Scientific (Thermo Fisher Scientific Inc., Waltham, MA). Secondary anti-mouse or anti-rabbit (1:5,000) alkaline phosphatase-conjugated antibodies were from Sigma (Milan, Italy). After electroblotting on nitrocellulose paper, the equivalence and homogeneity of the loaded samples were verified by staining the nitrocellulose membrane with Ponceau Red. The immunodecorated bands were visualised with a ready-to-use precipitating substrate system for alkaline phosphatase (BCIP/NBT liquid substrate system; Sigma). Images were obtained with an HP Scanjet scanner and Adobe Photoshop.
Densitometry was performed with Scion Image Software without modification of the images (raw images) to quantify protein band intensities.

Data are expressed as the means ± SE. Statistical analyses were performed using Origin 8.5 software. Student’s t-test was used for comparisons between data from wt/wt and knock-in CSQ2-R33Q/R33Q mice. Statistical significance was set at $P < 0.05$.

RESULTS

Western blot data showed that the amount of mutated protein was reduced early after birth, with a drastic reduction at 6 days (Figure 1). Subsequently, increased protein levels were observed at 9 days and 2 weeks. After 2 weeks, decreased levels of CSQ2-R33Q were observed, and protein levels reached a minimum at 8 weeks. Thus, the lowest levels of CSQ2-R33Q expression were observed at 6 days and 8 weeks (20% of the CSQ2 in wt/wt mice).

Triadin levels were also reduced in 8-week-old knock-in CSQ2-R33Q/R33Q mice. TD32 is the main cardiac isoform of triadin and is one of the proteins that anchor CSQ2 in proximity to RyR2. In control hearts, the TD32 content increased markedly and quickly after birth (Figure 2A). After 6 days, TD32 expression levels were 5-fold higher than those in 2-day-old wt/wt mice. However, after 6 days, TD32

Figure 1: CSQ2 protein levels compared between CSQ2-wt/wt and knock-in CSQ2-R33Q/R33Q mice of different ages (2DD – 2 days, 6DD – 6 days, 9DD – 9 days, 2 WKS – 2 weeks, 8 WKS – 8 weeks). CSQ2 expression levels of homozygous knock-in mice are expressed as the percentage of that of wt mice CSQ2 levels. (*) $P < 0.05$ same age comparison between knock-in CSQ2-R33Q/R33Q and CSQ2-wt/wt protein levels.

Figure 2: TD32 time course in CSQ2-wt/wt (A) and CSQ2-R33Q/R33Q (B) mice of different ages (2DD – 2 days, 6DD – 6 days, 9DD – 9 days, 14DD – 2 weeks).
levels began to quickly decrease in wt/wt mice. In knock-in mouse hearts, TD32 showed a different expression pattern, increasing slowly over time (Figure 2B). When TD32 levels in knock-in hearts were compared with controls at different ages, a drastic reduction in the protein levels early after birth (~50%) was observed, and this reduction remained constant at all ages (Figure 3).

This research was also directed towards the molecular analysis of 3 unfolded protein response (UPR) proximal effectors. The protein expression of one of these proximal effectors, transcriptional factor activating transcription factor 6 (ATF6), was analysed in different age groups of wt/wt and knock-in CSQ2-R33Q/R33Q mice. These analyses showed the presence of increased levels of the active form of ATF6 in 2-week-old knock-in CSQ2-R33Q/R33Q mice (Figure 4). The transcriptional activation of UPR target genes, including those that function as part of the ER protein-folding machinery (ER chaperones) such as calreticulin (CRT), glucose-regulate protein-78 (GRP78) and glucose-regulate protein-94 (GRP94), was also analysed. The results showed that all three analysed ER chaperones were up-regulated, with peak expression levels observed in the hearts of 2-week-old knock-in CSQ2-R33Q/R33Q mice (Figure 5). For example, GRP78 levels were five times higher in 2-week-old knock-in CSQ2-R33Q/R33Q mice than in wt/wt mice (Figure 5B). Unlike GRP78, GRP94 protein levels remained high in knock-in CSQ2-R33Q/R33Q mice even after 2 weeks (Figure 5C).

DISCUSSION

Calsequestrin is an acid glycoprotein with a moderate affinity (Kd = 1 mM) and high ability for binding to Ca^{2+}; it brings the total amount of Ca^{2+} within the SR to 20 mM and maintains the concentration of free Ca^{2+} at 1 mM (11). CSQ has a greater ability to bind Ca^{2+} in its polymeric form in the presence of 1 mM Ca^{2+}. The C-terminus of CSQ contains the highest density of amino acids and is forced to form a Ca^{2+}-binding pocket in polymeric form (12). CSQ plays an important role as a Ca^{2+} buffer and regulates the activities of RyR in relation to the Ca^{2+} concentration in the SR lumen (13). Furthermore, CSQ, together with triadin and junctin, was proposed to play an important role in SR junction development (14). As proposed by Beard (11), CSQ may also act as a chaperone through its kinase activity to ensure the correct folding of proteins present in the SR lumen and most likely plays an important role in removing toxic substances from the SR.
lumen. CSQ is present in the lumen of the SR terminal cister- 
ternae as a linear polymer and is anchored to RyR via two 
transmembrane proteins, triadin and junctin, forming the 
Ca2+ release channel complex (11).

Presently, 8 recessive mutations in the csq2 gene have 
been linked to CPVT. Four of them are non-sense muta-
tions that generate premature stop codons, while the other 
four are point mutations (15-17). The unique characteris-
tic of each mutation can alter the clinical phenotype of the 
disease (18). In these analyses, we chose specific criteria to 
obtain complete information regarding postnatal develop-
ment; thus, we have a detailed picture of the events triggered 
by the presence of the CSQ2 R33Q point mutation. The first 
age used was as close to birth as possible (2 days); then, 1 
week after birth was used. Nine-day-old mice were chosen 
for molecular analysis because this age represented an in-
termediate time point between the first and second weeks. 
Two weeks after birth was considered a critical time point 
for the cardiomyocyte based on the results of previous stud-
ies (10) that showed the appearance of optimal morphologi-
cardiac myocyte characteristics at this point, which were 
responsible for the correct functioning of the heart muscle 
in adulthood. Finally, as reported by Flucher and Franzini-
Armstrong, 8 weeks was considered a good point to analyse 
adult hearts (10). The mutated protein levels were analysed 
first, using the wild-type protein levels as a control. CSQ2-
R33Q is CSQ2 with a mutated amino acid in position 33; 
this mutation did not seem to affect the secondary or terti-
ary conformation of the overall protein (29). The CSQ2 mu-
tation knock-in mouse (9) was characterised in vitro and in 
vivo and was demonstrated to be an identical copy of the 
patient phenotype. CSQ2 and triadin protein levels were 
reduced, while the corresponding mRNAs levels remained 
unchanged (9). The CSQ2-R33Q protein levels found in this 
study confirmed the results of Rizzi and colleagues (9), who 
reported that CSQ2-R33Q proteins levels were significantly 
lower than wild-type protein levels. Comparison of the re-
results reported in Figures 2A and 2B suggested that TD32 
levels decreased due to the lack of functional CSQ2 from 
birth in the CSQ2-R33Q/R33Q mice. Results from a previ-
ous study (19) also showed that CSQ2 protein levels were 
significantly reduced in adult Trdn -/- mice. The mechanism 
of the post-transcriptional control of unfolded proteins can 
explain the reduction of CSQ2-R33Q protein levels without 
effect on mRNA content.

ER stress is defined as an imbalance between the load of 
unfolded proteins that enter the ER and the capacity of the 
cellular machinery to handle this load; ER stress results in a 
series of different responses. In eukaryotic cells, the major-
ity of secreted and trans-membrane proteins are synthesised 
and matured in the ER lumen. Proteins enter the ER as un-
folded polypeptide chains. The incorrect folding of nascent 
proteins may occur in response to many environmental 
stresses or as a result of mutations that disrupt the protein 
structure. An imbalance between the load of unfolded pro-
teins entering the ER and the ability of the cell machinery 
to handle this load is defined as ER stress, which triggers a 
series of responses known as the UPR (20). When ER stress 
occurs, three ER transmembrane sensors are activated to 
initiate adaptive responses. These sensors include protein 
kinase-like ER kinase (PERK), inositol-requiring kinase 1 
(IRE1), and ATF6. The N-termini of these transmembrane
UPR sensors are located inside of the ER lumen and the C-termini are within the cytosol, thereby connecting the ER lumen to the cytosol. All three sensors are maintained in an inactive state through the interaction of their N-termini with GRP78. When unfolded proteins accumulate in the ER, GRP78 releases these sensors, allowing for their oligomerisation and initiation of the UPR. Under these conditions, GRP78 translocates into the ER lumen, binds proteins and facilitates their folding. At the same time, IRE-1, ATF6, and PERK are activated and induce the transcription of ER stress response genes (21). To analyse the signal transduction cascade involving PERK, attention has focused on the expression of ribosomal protein eIF2α, a translation initiation factor. Phosphorylation of eIF2α by PERK leads to the decrease of most mRNA translation (22). This first response to ER stress reduces the load of proteins that must enter the ER. This is a transient form of adaptation that is realised by slowing the synthesis and translocation of protein into the ER lumen. Preliminary results have shown an up-regulation of phosphorylated eIF2α expression in 2-week old knock-in CS2R33Q/R33Q mice. The inactive form, eIF2α-P, lowers the levels of newly synthesised proteins. Subsequently, the capacity of the ER to handle unfolded proteins is increased, representing a more long-term adaptation that entails transcriptional activation of UPR target genes, including those that function as ER chaperones such as CRT, GRP78 and GRP94.

The activated form of ATF6 plays an important role in the synthesis of chaperones such as GRP78 and CRT (23). This was confirmed by experimental data showing that in 2-week-old mice, increased ATF6 levels corresponded to the highest, statistically significant expression levels of GRP78 (Figure 5B) and CRT (Figure 5A). Results in the literature show that ERAD is activated if it is not possible to restore the balance. ERAD provides 1) the recognition of incorrectly folded proteins, 2) translocation of such proteins into the cytoplasm, where they are bound to numerous ubiquitin molecules and 3) degradation via the proteasome (24). GRP94 is thought to play an important role in the response to incorrectly folded proteins, participating in their translocation from the ER lumen to the cytosol (25). Unlike GRP78, GRP94 protein levels remained high in knock-in CSQ2-R33Q/R33Q mice even after 2 weeks (Figure 5C). This indicated the possible activation of ERAD. Therefore, in accordance with these experimental data, it was speculated that the R33Q mutation induced structural and/or functional changes to CSQ2 that led to UPR activation and subsequent CSQ2 degradation. Thus, the reduction of CSQ2-R33Q might be due to its degradation via ERAD. Proteins with serious folding errors and protein aggregates are degraded by autophagy. In fact, many of the components that mediate autophagy are UPR target genes (26). If ER stress is permanent and irreparable, the process of apoptosis is activated and leads to cell death (27). Thus, it is of extreme interest to extend analyses to markers of autophagy and apoptosis such as CHOP, an ER stress-associated proapoptotic transcription factor (28).

CONCLUSIONS

These study results showed that mutated CSQ2 levels decreased soon after birth in conjunction with the decreased levels of other important junctional SR proteins such as TD. The up-regulation of proteins associated with the UPR was also observed; this led to ATF6-dependent pathway activation by the UPR. The R33Q mutation induced the decrease of CSQ2 levels through UPR activation and subsequent proteasomal degradation. Further studies are necessary to confirm these results.
